O. D. + 5.s \bigcirc + .75c axis H $\frac{2}{3}$. O. S. + 5s. \bigcirc + .90c axis 15 $\frac{2}{3}$. Three months later this patient reported herself better in every way, having had only one headache and no eye pain.

Case 28. Ordinary School Headaches.—B. B., a

girl aged 16, has worn glasses for four years, very much an under correction of her refraction error and without note of the astigmatism. She is subject to tonsillitis, has some indigestion and a great many comedones on her face, probably connected with the indigestion, perhaps with menstrual disturbance; complains of indistinct vision and headache coming on after school, with inability to maintain accurate close vision. In the right eye an oval disc, the surface a little woolly, and a slight crescent at the outer side. In the left eye an irregularly oval disc with distinctly mellowed edges and many lymph reflexes through the fundus.

O. D. + 2.5 \odot + .12c axis H $\frac{2}{3}$. O. S. + 3.25s \odot + 1.25c axis 15 $\frac{2}{3}$. Several months after this correction was ordered marked relief was reported.

Case 29. Occasional Brow Pain; a Good Deal of Nervousness.—J. J. R., a woman aged 35, was glassed six years ago, and wears a correction similar to the one given below, but slightly under the total amount of astigmatism; declares that she is in good general health, a report which is confirmed by her physician; complains of limited eye endurance, headache over the brow and pain darting in the right eye; cannot use the eyes at night, and "gets nervous from her eyes." In each eye a typical eye strain appearance, namely: slightly veiled edges of the disc, full lymph sheaths, fine œdematous haze of the retina.

O. D. + 2.5 \odot + .90c axis 165 $\frac{2}{3}$. O. S. + 1.75s \odot + .90c axis H $\frac{2}{3}$. A month later she reported progress, but still complained of some pain and the nervous feeling when she used her eyes. The eye-grounds were still very irritable.

Case 30. Post-ocular Headache.—A. A., a woman aged 38, has worn glasses for ten years, recently having a correction closely similar to the one given below, but also an under-correction; she is closely confined at her business and is in poor general health from lack of exercise, without any definite illness; is very nervous. The eyes feel strained, and their use brings on severe pain situated behind the orbit. In each eye a round disc with a shallow excavation, the papilla being surrounded by a somewhat hazy retina.

O. D. + 2.5 \odot + .50c axis 30 $\frac{2}{3}$. O. S. + 1.75s \odot + .75c axis 150 $\frac{2}{3}$. These glasses were a help, but a vacation, complete rest, and some general medication were also used.

Case 31. Temporal Headache; Ocular Pain.—A. R. L., a man aged 29, uses his eyes a good deal; is a trained athlete and in general good health; formerly he was subject to vertigo which now has entirely subsided; at present complains of pain in the eyeballs nearly constant, and when headaches come on, which is not infrequent, the pain is situated in the temples. In each eye an oval hyperæmic optic disc, the eyegrounds showing superficial choroidal disturbance.

O. D. + 1.25s \odot + .25c axis 165 $\frac{2}{3}$. O. S. + 1.25s \odot + .25c axis 15 $\frac{2}{3}$. These glasses appear to have given comfort thus far, but the eyegrounds are far from being in good condition and rest has been enjoined.

In these thirty-one cases various types of headaches occurred, which, when due to eye-strain owing to the existing error of refraction, were relieved promptly by the correction except when the pain had evident origin in some constitutional condition, namely, in cases 1 and 3; and when, as in cases 15, 18, and 29, although no exact constitutional reason for the headache was ascertained, the general system probably was at fault, or sufficient time for the irritability of the eyegrounds to subside had not yet elapsed. In other words, the relief was exactly the same as that which is afforded by the correction of the ordinary errors of refraction associated with headache. It did not seem in any of the cases that the headache was more severe than that often noted in cases of astigmatism according to the rule, nor was there in any case marked general disturbance, as the apparent result of the eye-strain, except, perhaps, in case 7, where a feeble young woman improved greatly in all respects without the use of any general medication. In several cases general tonic medication was employed in addition to the optical therapeutics—a precaution often advisable as an adjunct in the treatment of "eye-strain" headaches. The ages of these patients varied from 13 to 61 years.

Four cases characterized by ocular changes—incipient cataract, with or without headache; and glaucoma.

Case 1. Simple Chronic Glaucoma.—S. E., a woman aged 50; has had much mental worry, otherwise no illness; dim vision in the right eye for several months; frequent changes in glasses; periods of obscuration of vision; no headache. Right eye, round disc excavated to margin, especially deep above and to nasal side, buff-colored rim with halo all round. T. plus 2. Left eye, round disc, small central excavation; veins full and pulsating. Anterior chamber in both eyes shallow; the nasal field in O.D. absent; in O.S. contracted.

O. D. + 2.5 \odot + .60c axis 15 $\frac{2}{3}$. O. S. + 2.25s \odot + .60c axis H $\frac{2}{3}$. Twenty months later the central vision in O.D. was $\frac{2}{40}$; in O.S. $\frac{2}{20}$. The patient has used continuously eserine. The field of vision has not materially changed.

Case 2. Simple Chronic Glaucoma.—A. H. D., a woman aged 65; easily worried; a poor sleeper; has chronic dyspepsia; obscured vision in the right eye above the horizontal line; pain in the back of neck; many changes in glasses. In the right eye a narrow anterior chamber; nerve horizontally oval; complete, shallow, glaucomatous cup and halo; T plus 1. In the left eye oval

disc; partial excavation; halo-like band. In the field of the right eye there was complete loss of the upper and inner quadrant; in the left contraction of the lower inner portion.

O.D. + .50s \bigcirc + .50c axis $15 \frac{2}{3}$. O.S. + .50s \bigcirc + .50c axis $165 \frac{2}{3}$. Iridectomy has been done on the right eye in this case, with good result.

Case 3. Incipient Cataract; Ocular Pain.—C. S., a woman aged 70; well preserved; general health, except for rheumatism, good; unsatisfactory reading glasses—simple convex sphericals; eyes pain. Oval discs; sharp scleral rings; choroids fair; striæ in the anterior cortices.

O.D. + 2.50s \bigcirc + .75c axis $15 \frac{1}{2}$. O.S. + 2.50s \bigcirc + .60c axis $165 \frac{1}{2}$. The result was increased comfort to the patient.

Case 4. Incipient Cataract; Occipital Headache.—S. A., a man aged 54; is the subject of muscular rheumatism and occipital headache; eyes readily tire at close work. Irregularly oval, gray discs; sharply marked scleral rings; fine, dust-like opacities in the periphery of each lens.

O.D. + .25c axis $15 \frac{2}{3}$. O.S. plus .25c axis $165 \frac{2}{3}$. These cylinders, incorporated with suitable convex sphericals for reading purposes, gave great satisfaction. Iodides, however, were ordered.

Case 5. Incipient Cataract; Occipital Headache.—W. W. G., a woman aged 54; imperfect health, although complexion ruddy; asthma (renal?); occipital headache; trigeminal neuralgia; reading glasses unsatisfactory; many follicular granulations in the conjunctival cul-de-sac. Oval, gray discs and fine striæ in the anterior cortex of each lens; albumen, hyaline and granular casts in the urine.

O.D. + 2.50s \bigcirc + .25c axis $H \frac{2}{3}$. O.S. + 2.5 \bigcirc plus .25 c axis $165 \frac{2}{3}$. The result of the change of glasses in this case was at last accounts not a satisfactory improvement. The local condition of the conjunctiva precluded the possibility of any eye work.

Case 6. Incipient Cataract; Frontal Headache.—B. C. G., a woman aged 60; general health moderately good; subject to "sick headaches;" at times bilious; urine normal; eye pain with sharp frontal headache caused by reading; glasses—simple convex spherical—not satisfactory. Small oval discs with yellowish dots in the macula; many shoots in the periphery of each lens.

O.D. plus 1.75s \bigcirc plus .90c axis $150 \frac{2}{3}$. O.S. plus 2.5 \bigcirc plus .50c axis $60 \frac{2}{3}$. Distinct relief has followed the new correction. The patient, however, has taken alternately iodide and bromide of potash, and strychnia.

Case 7. High H As.; Incipient Cataract.—T. A. H., a woman aged 68; general health moderately good; sciatica at times and occasional

attacks of bronchitis; convergent squint since childhood; seeks advice for improvement in vision; wears sphericals only; no headache. Oval, rather grey-red discs with mellow margins. Incipient cataract in each eye.

O.D. plus 2.50s \bigcirc plus 2.c axis $150 \frac{2}{3}$. O.S. plus 4.s 1.50c axis $165 \frac{2}{3}$. The improvement in vision, which was considerable, afforded the patient great satisfaction.

Case 8. Incipient Cataract; Pain in the Occiput.—E. C., a woman aged 61, has a mitral murmur and complains of pain after reading, sewing and the like, with some smarting and burning of the eyelids and pain in the occiput. In each eye an oval, distinctly gray optic disc. In the right eye the lens hazy, in the left striæ in the anterior cortex.

O.D. plus 4.50s \bigcirc plus .75c axis $H \frac{2}{3}$. O.S. plus 4.50s \bigcirc plus .25c axis $H \frac{2}{3}$. These glasses afforded her considerable relief, although prolonged reading still produces some burning in the eyelids.

Case 9. Incipient Cataract; Vertigo; Occipital Headache.—J. V. B., a woman aged 58, suffers from chronic indigestion and vertigo of such a type that the tendency is to fall forward; occasional attacks of severe headache in the occiput; heart and kidneys normal. In each eye an apparently healthy optic disc, except for undue broadening of the scleral ring. Large flocculent opacities in the anterior cortex of each lens, not yet encroaching upon the pupillary space.

O. D. plus 1.s \bigcirc plus .50c. axis $H \frac{2}{3}$. O. S. plus 1.s \bigcirc plus .50c axis $H \frac{2}{3}$. These glasses afforded relief, but it should be stated that the patient was also under treatment for the chronic indigestion, and no doubt the regulated diet and medicinal measures were potent factors in relieving the vertigo. The headache appears to have been due to uncorrected astigmatism. The patient has not reported quite lately, and the present result is unknown. It is an interesting fact that through the distance glasses there was orthophoria for the distant point; without them a slight right hyperphoria.

Case 10. Incipient Cataract; no Headache.—J. E. W., a woman aged 70, complains of no headache, but some slight pain in the eyeballs; uses her eyes incessantly as an artist doing the finest kind of painting. With the exception of some dyspepsia and a recent attack of influenza, the general health is good. In each eye there are striæ in the anterior cortex, radiating irregularly towards the pupil. Each disc is oval, gray, and its central lymph sheath full. The maculas are normal.

O. D. plus 1.25s \bigcirc plus .75c axis $H \frac{2}{3}$. O. S. plus 2.s \bigcirc plus .25c axis $H \frac{2}{3}$. The patient expressed satisfaction with the glasses.

Case 11. Incipient Cataract; Slight Conjunctivitis.—W. T., a man aged 62, in good general health with the exception of an attack of influenza, from

which the convalescence was slow, complains that the right eye inflames, the vision is dim and the glasses not clear; there is no headache. In each eye an oval disc, with undue broadening of the scleral ring, and the surface distinctly gray-red. In each lens small opacities down and in, in the anterior cortical, and the circle surrounding the nucleus slightly hazy.

O. D. plus .50s \bigcirc plus 1.25c axis H $\frac{2}{3}$. O. S. plus .90c axis 150 $\frac{2}{3}$. These glasses, together with simple sphericals, were ordered. The patient appeared to see with satisfaction, but complained still of irritation, the irritation so common in incipient cataract. It should be stated that there was also some squamous blepharitis.

Case 12. Incipient Cataract; Slight Vitreous Opacities; Occipital Headache.—J. A., a man aged 61, has had rheumatism, but with the exception of an attack of influenza in last October, which much prostrated him, has been in good condition. Since then has complained of floating spots before the right eye; he has some headache, chiefly in the occiput. In the right eye an oval, rather gray disc, fine haze in the vitreous and some striæ in the lens. In the left eye the conditions are similar, except no vitreous change was noticed. In each the retinas were hazy.

O. D. plus 1.25s \bigcirc plus .50c axis H $\frac{2}{3}$. O. S. plus 1.s \bigcirc plus .50c axis H $\frac{2}{3}$. The vision, however, was not clear, but seen through a slight mist, especially on the right side.

Case 13. Incipient Cataract; Pain in the Eyeballs.—J. B., a man aged 58, complains of some pain in the eyeballs, worse upon the left side; occasional brow ache. With the exception of a severe fall in the winter, which shocked him considerably but did not break any bones, there has been no noteworthy fact in his recent history. There is a slight haze around the perinuclear tissue of the lens, and a few fine opacities. Each disc is gray-red and contains a small central cup; in each macula a few fine yellowish dots.

O. D. plus 1.s \bigcirc plus .75c axis 150 $\frac{2}{3}$. O. S. plus 1.s \bigcirc plus .50c axis H $\frac{2}{3}$. These glasses were ordered and eye rest enjoined.

Case 14. Incipient Cataract; Some Throbbing in the Temples.—P. J., a man aged 68, considers himself to be in good general health; has some post-nasal catarrh; complains recently of some throbbing in the temples and insufficient eye endurance. In the right eye an irregularly horizontal oval disc, with slightly mellowed edges, and an atropic broadening of the scleral ring. There is superficial absorption of the choroidal pigment. In the left eye a rim of cortical opacities not yet encroaching upon the pupil, an oval disc which is very gray, and considerable epithelial choroidal change.

O. D. plus 1.s \bigcirc plus .60c axis 165 $\frac{2}{3}$. O. S. plus 1.50s \bigcirc plus .50c axis 15 $\frac{2}{3}$.

Case 15. Incipient Cataract; Headache and Nau-

sea.—J. A. T., a woman aged 55, six years ago suffered from nervous prostration, since then has been exceedingly nervous and suffered from flitting neuralgic pains; the nervousness is increased by reading, which also brings on headache associated with nausea. In the right eye there is a slightly gray, oval disc, without conus; small, fluffy opacities in the lens. In the left eye a similar oval disc and similar opacities, one spear-shaped stria passing towards the pupil space. Here and there in the choroid fine yellowish dots.

O. D. plus .25c axis H $\frac{2}{3}$. O. S. plus .50c axis 165 $\frac{2}{3}$. This was added to a suitable presbyopic correction and worn with a good deal of satisfaction—the patient, however, was put upon a restricted reading diet and given alteratives, chiefly in the form of bichloride of mercury.

The two cases of glaucoma are interesting in connection with Dr. Theobald's investigations as to the possibility of astigmatism being a factor in the development of this disease. They are further interesting because of the sharp central vision which was obtained by a correction of the astigmatism, and the influence of instillations of eserine. Both of these cases had been entirely unconscious of any serious eye trouble, and wondered why the frequent glasses which they purchased without consultation had never permitted them to see well or comfortably. The thirteen cases of incipient cataract were all, up to the present date, relieved by the addition of the cylinders to their reading glasses and the use of the correction for constant wear, with the single exception of the case associated with Bright's disease and granular lids, although in three of them no marked change for the better can be recorded. The importance of the correction of the entire error of refraction in incipient cataract has been dwelt upon frequently, especially in the able communication of Dr. S. D. Risley¹ upon this topic. It is, perhaps, worth while to emphasize the fact that the very presence of striæ in the lens determines an astigmatism against the rule, and that this should be searched for and corrected; and moreover, that these corrections should be the subject of re-examinations at stated periods, because the refraction must necessarily change in eyes the lenses of which are swelling under the influence of cataract formation. With such correction, however, aided by alteratives and tonics, much of the distress, either in the eyes themselves, or in the head, in the form of headache, which not infrequently is associated with the early stages of cataract, may be alleviated. In this particular it is necessary only to refer again to Dr. Risley's paper. I would call attention to the good central vision which was obtained in the incipient cataract cases when the opacities were still in the periphery, and had not encroach-

¹ University Medical Magazine, March, 1889.

ed upon the pupil space. The ages of these patients varied between 50 and 70.

5. Cases characterized by various types of headache and associated nervous phenomena bordering on the type of the so called "reflex neuroses."

Case 1. Subjective Vertigo.—K. E., a woman aged 57; general health moderate; constipated and has hæmorrhoids; much eye pain, lachrymation and distress when at close work; for the last six months vertigo, sudden and subjective, when looking to the right. Discs gray and general absorption of the pigment epithelium of the choroid. Discs on a lower level than the maculas.

O. D. plus .25s \bigcirc plus 1.25c axis 15 $\frac{1}{15}$. O. S. plus .75s \bigcirc plus 1.c axis 165 $\frac{1}{15}$. The use of laxatives and regulation of the general condition did not relieve the vertigo; the glasses did.

Case 2. Occipital Headache; Melancholia.—D. S., a woman aged 48; general health good at present; occasional attacks of depression; has had two periods of melancholia once requiring sequestration; severe occipital headache; muscæ. Oval discs, rather gray, with a patch of choroiditis at the outer side of each.

O. D. plus .50s \bigcirc plus .50c axis 15 $\frac{1}{15}$. O. S. plus .50s \bigcirc plus .50c axis 165 $\frac{1}{15}$. These glasses afforded practically entire relief to the occipital headache. Owing to a high grade of insufficiency of the internal recti (exophoria), the corresponding reading glass was combined with prisms. There have been no attacks of melancholia since, and the woman's spirits are better, but the previous attacks of melancholia were so directly connected with grave disasters in the patient's immediate family that it would require a stretch of imagination to think that the eye strain had had ought to do with their production.

Case 3. Marked Asthenopia; Typical Neurasthenia.—T. W., a woman aged 67; reasonable general health; marked asthenopia; cannot read for five minutes; easily depressed; has attacks of "night ptosis." Discs gray with visible scleral rings, and fibre layers of the retinas somewhat opaque.

O. D. plus 2.s \bigcirc plus .90c axis H $\frac{1}{15}$. O. S. plus 2.s \bigcirc plus .75c axis H $\frac{1}{15}$. Great improvement followed the use of these glasses, and while the asthenopia has not disappeared entirely, the eye endurance has markedly improved. With this improvement in eye-tire the previous depression of spirits has disappeared correspondingly. In this case there was also a high insufficiency of the internal recti, and prisms were combined with the reading glasses. The "night ptosis," or in other words, a contracture or dropping of the upper lid which came on during the night, especially if the eyes had been used during the earlier evening, making the patient desire to "prop up her lids," which she declared she could not voluntarily raise, is a curious symptom that I have

twice noted in patients suffering from asthenopia and allied ocular conditions, and who were as well the subjects of general hysterical manifestations.

Case 4. Frontal and Occipital Headache; General Nervousness.—P. G. J., a woman aged 53; chronic acid dyspepsia; eyes pain; cannot get glasses to suit; severe frontal and occipital headache follows eye use at close ranges, which results in attacks of general nervousness unfitting her for her ordinary duties. Fundus healthy, but the discs rather pallid.

O. D. plus 1.s \bigcirc plus .25c axis H $\frac{1}{15}$. O. S. plus 1.s \bigcirc plus .50c axis H $\frac{1}{15}$. The result in this case was very satisfactory.

Case 5. Fugitive Headache; Taciturn, Morbid and Moping.—J. H. L., a girl aged 13; beginning to menstruate; much headache unrelieved by general medication; photophobia; moping; unnaturally quiet, indisposition to any exertion. Discs with blurred edges, many lymph reflexes and hazy retinas.

O. D. plus 1.50s \bigcirc plus .75c axis H $\frac{2}{9}$. O. S. plus 1.50s \bigcirc plus .25c axis H $\frac{2}{9}$. Great relief followed, but the ocular treatment was associated with the use of iodides, bromides, iron and ergot. For a number of months she remained free from trouble, became more cheerful and pursued her ordinary duties; then a relapse took place, characterized especially by photophobia, following an attack of fever somewhat remittent in type. The case has again improved without recorection by the aid of bromide and ergot. The glasses were certainly one of the factors in relieving the general nervous symptoms in this case.

Case 6. Occipital Headache; Vertigo.—B. N., a man aged 46; general health good; recurring attacks of congestion of the bulbar conjunctiva; occipital headache; aggravated vertigo. Horizontally oval, gray discs with absorption of the pigment epithelium.

O. D. plus 1.s \bigcirc plus .50c axis 165 $\frac{2}{9}$. O. S. plus 1.s \bigcirc plus .25c axis 15 $\frac{2}{9}$. In this case the correction did not relieve the vertigo, or had not done so at the patient's last report some time since. The headache was relieved and the reading power increased, but otherwise the ocular therapeutics were not sufficient to subdue the chief symptom for which he presented himself—vertigo.

Case 7. General Headache; Insomnia.—G. M., a man aged 64; has chronic gout; severe headache increased by eye use; reading well nigh impossible; aggravated insomnia. Horizontally oval discs, gray; many yellow dots in the macula; urine normal.

O. D. plus 2.25s \bigcirc plus .50c axis 15 $\frac{2}{9}$. O. S. plus 2.50s \bigcirc plus .60c axis 165 $\frac{2}{9}$. Great relief, as far as the headaches were concerned, followed the use of this correction. The insomnia also was markedly relieved, but this has fluctuated

very much according to the man's general condition and the absence of presence of gouty symptoms.

Case 8. Right sided Headache; Excessively Nervous.—E. F., a woman aged 34; has casts and albumen in the urine; severe right-sided headache with pain in the eyes, the use of which caused great nervousness; weeps readily; is depressed; globus not present.

O. D. plus 3.5 \bigcirc plus .25c axis 165 $\frac{20}{0}$. O. S. plus 3.25 \bigcirc plus .50c axis 15 $\frac{20}{0}$. There was entire relief of the headache, and with its relief the irritable nervousness was materially calmed. The patient was under treatment, also, for the coexisting Bright's disease, and it was difficult, owing to its presence, to determine which headaches belonged to eye-strain and which to the kidney disease, and also which one of these two factors was to blame for the excessive nervousness which amounted in its sum to manifestations closely resembling hysteria.

Case 9. Constant Morning Headache; Hypochondriasis.—W. L. H., a man aged 42; organs sound, but very nervous and despondent; thinks he has brain tumor and various other organic lesions; has had much mental worry; troublesome morning headache. Horizontally oval discs, rather gray. No change in the fields of vision.

O. D. plus .75s \bigcirc plus .50c axis 30 $\frac{20}{0}$. O. S. plus .50s \bigcirc plus .60c axis 165 $\frac{20}{0}$. There was gradual but decided relief of all symptoms; this, however, became complete only when a tonic regimen, systematic exercise and massage were added. The improved ability in reading and the disappearance of the morning headache were decided factors in relieving the mental depression.

Case 10. Occipital Headache; Vertigo.—D. M. J., a woman aged 44; general health poor; has chronic cystitis; has general vertex and occipital headache with a bruised feeling in the eyeballs; very distressing vertigo, especially when walking on the street. Slightly pallid discs with mellow edges, and fine, dust-like opacities in the anterior cortices.

O. D. plus .90c axis 15 $\frac{20}{0}$. O. S. plus .60c axis 165 $\frac{20}{0}$. These glasses afforded almost entire relief to the head symptoms with the exception of the vertex pain which persisted. The vertigo also disappeared. This is a good example of the fact that patients often suffer with two kinds of headache, the vertex headache being in this case almost certainly associated with pelvic disorders.

Case 11. Headache; Nervous Prostration; Vertigo with Nausea.—J. P., a woman aged 45; has had several attacks of nervous prostration; eye work causes nausea; general nervousness; this is apparent, especially when the eyes are used at distances midway between those which come into play in reading or close work, and at twenty feet or beyond. The fundus is normal.

O. D. plus .50s \bigcirc plus 1.50c axis 15 $\frac{20}{0}$. O. S. plus

1.50s \bigcirc plus .50c axis H $\frac{20}{0}$. The glasses in this case, which was seen in consultation, have afforded partial relief; certainly since their use the patient is said to be in a more satisfactory condition, and thus has reported herself, but is not entirely free from the symptoms above detailed. There appears to be no organic disease.

Case 12. Vertigo.—C. E., a woman aged 45; general health good; menopause not yet begun; recent severe and constant vertigo. Oval discs with broad scleral rings.

O. D. plus .37c axis H $\frac{20}{0}$. O. S. plus .50s \bigcirc plus .25c axis 60 $\frac{20}{0}$. The relief of the vertigo began with the use of the mydriatic, but the patient is also under general treatment.

Case 13. General Headache; Nausea; Muscular Twitchings.—S. C., a woman aged 29; complete nervous breakdown; muscular twitchings; insomnia; constant severe headache beginning as frontal and becoming general; eye-work causes nausea, increased headache, excessive nervousness and insomnia; organs sound. The fundus is normal except for some retinal haze.

O. D. plus 1.5 \bigcirc plus .75c axis 15 $\frac{20}{0}$. O. S. plus .50s \bigcirc plus 1.c axis 165 $\frac{20}{0}$. Relief began with the mydriatic, and up to the present time the patient is better. She, however, at the same time is having massage. The case is still under observation, and the date too soon to state positively the ultimate result.

Case 14. Sensation of Falling Forward when Walking in a Crowd; Confusion of Ideas.—M. P. F., a man aged 35; up to two years ago in good health; then an attack resembling epilepsy, but probably not epileptic; since then has had frequent attacks of mental confusion with a sense of falling forward, especially if walking on a crowded street; no general disease discovered. The fundus is perfectly normal, except a few yellow dots near maculas.

O. D. plus 1.5 \bigcirc plus .50c axis H $\frac{20}{0}$. O. S. plus 1.5 \bigcirc 50c axis H $\frac{20}{0}$. There has been only one attack since the patient was glassed. He is still under observation, which has extended over many weeks. He has taken no general medication.

Case 15. Severe Headache; Neurasthenia Globus Hystericus.—S. E., a woman aged 35; very gouty ancestry; vertex and occipital headache; marked neurasthenia; globus hystericus at times; keeps eyes closed. Fundus normal except for slight retinal haze.

O. D. plus .50c axis 15 $\frac{20}{0}$. O. S. plus .50c axis 165 $\frac{20}{0}$. All symptoms better.

Case 16. Frontal and Occipital Headache; Nervous Prostration.—C. S., a man aged 60; in poor general health; recent complete nervous breakdown forbidding, in large measure, any mental labor; unable to read satisfactorily; dull occipital and sharp frontal headache; recently had

an injury followed by typhoid symptoms (septicæmia?); media clear. Horizontally oval discs with mellow edges and deeper layers gray.

O. D. plus .50s \bigcirc plus .25c axis 15 $\frac{2}{3}$. O. S. plus .75s \bigcirc plus .60c axis 165 $\frac{2}{3}$. Distinct improvement in reading power and mental effort followed the use of this correction. It is quite evident in this case, however, that the nervous prostration was the result of the shock occasioned by the injury, and the patient is now undergoing a rest treatment.

Case 17. General Headache; Excessive Nervousness and Paræsthesia of the Face and Throat.—M. H., a woman aged 57; general health good and organs sound; for some years pricking sensations in the face and throat; occasional right-sided neuralgia; headache, and general nervousness, excessive after eye use. Oval, rather gray disc; a few spicules in the left lens.

O. D. plus 3.s \bigcirc plus 1.c axis H $\frac{2}{3}$. O. S. plus 3.50s \bigcirc plus .50c axis 30 $\frac{2}{3}$. Relief has followed the treatment in this case which, however, did not consist alone in the prescription of glasses.

Case 18. Trigeminal Neuralgia; Vertigo or Faintness after Reading.—A. G. W., a woman aged 56, fourteen years ago had ptosis of the right side, the remains of which are still apparent; general health now good, but complains of dim vision, easily tired eyes, sometimes a subjective vertigo, or perhaps more accurately, feeling of faintness, and very constant attacks of trigeminal neuralgia. There is much eye trouble in the family. The father is blind from glaucoma and the brothers and sisters are all hypermetropic and astigmatic to a considerable degree. The ophthalmoscope revealed oval optic discs with unduly broadened scleral rings; no cupping; the media clear; and the retinas fairly healthy.

O. D. plus .50s \bigcirc plus .60c axis 150 $\frac{2}{3}$. O. S. plus 1.s \bigcirc plus .60c axis H. $\frac{2}{3}$. These glasses relieved the faintness or vertigo, but had no influence upon the trigeminal neuralgia, which is probably connected with a gouty taint that runs through the family.

Case 19. Occipital Headache; Insomnia.—L. D., a man aged 49, complains of burning in his eyes after reading for a short time, also of brow and occipital headache; he has stubborn insomnia. He uses simple convex sphericals for reading. The patient for many years has had chronic diarrhœa and leads a very sedentary life. The ophthalmoscope reveals in each eye a pallid, oval optic disc, with clear edges and reasonably healthy retinas.

O. D. plus .50s \bigcirc plus .50c axis 165 $\frac{2}{3}$. O. S. plus .50s \bigcirc plus .50c axis H $\frac{2}{3}$. These glasses combined with a suitable presbyopic correction, were efficient in relieving the local inconvenience to his eyes and the headache, but had no influence upon the insomnia. This was in all probability connected with his anæmic condition which

in its turn was secondary to the chronic diarrhœa. So, also, the headache was not entirely relieved, depending also probably largely upon constitutional causes.

Case 20. Ocular Pain; Neurasthenia.—J. M., a man aged 61, has broken down from business strain and complains of unequal vision, sore eyeballs and pain in the head. In the right eye the disc is a large oval, pallid, the edges slightly mellow; in the macula are a few spots of choroidal degeneration; in the left eye a similar disc but no macular changes. Neither syphilis, albumen, sugar, nor demonstrable atheroma of the vessels was present.

O. D. plus 1.s \bigcirc plus .50c axis H $\frac{2}{3}$. O. S. plus 1.s \bigcirc plus .50c axis H $\frac{2}{3}$. These glasses appeared to prove satisfactory; the patient, however, was upon a very carefully regulated course of treatment including a modified type of the rest cure with massage, electricity, etc., and consequently the effect of the glasses, except as aids to vision, cannot be estimated.

Case 21. Persistent Subjective Vertigo.—D. V. R., a man aged 56, who leads an active life, of full habit, a martyr to rheumatism, having had both endo- and pericarditis, and once an attack of peritonitis, for three months has had persistent vertigo. His present glasses, convex sphericals both for distance and reading, serve him a good purpose, but do not control the vertigo. In each eye an oval, gray-red optic disc, with mellowed and veiled nasal edges, exhibiting, in short, the appearances of a low grade neuritis.

O. D. plus .50s \bigcirc plus .75c axis 30 $\frac{2}{3}$. O. S. plus .50s \bigcirc plus .50c axis H $\frac{2}{3}$. The fields are distinctly contracted. There is right hyperphoria which fluctuates between one and four degrees. Diplopia is denied. These glasses afforded relief especially when combined with a prism base down before the right eye, but they did not cure the vertigo, which in this case was so evidently connected with circulatory disturbances. It is interesting, however, that they were distinctly a factor in such relief as the patient obtained.

Case 22. Vertigo and Pain in the Back.—F. P. C., a man aged 47, is compelled to use his eyes a great deal and complains of dizziness and pain in the back; his personal history is good; his digestion rather poor; he has had two severe illnesses in his previous life, once typhoid fever and once varioloid. Each optic disc was a vertical oval and contained a large physiological cup. There was some broadening of the scleral ring and slight retinal haze; in each macula fine yellowish dots; the urine, however, was normal.

O. D. plus .60c axis 165 $\frac{2}{3}$. O. S. plus .60c axis H $\frac{2}{3}$. Glasses may fairly be credited with having relieved the dizziness.

Case 23. Headache; General Neurasthenia.—D. W. M., a woman aged 60, of great activity, after prolonged mental strain broke down and

presented a series of neurasthenic symptoms, associated with severe pain in the back of the head, rather of the character of soreness than anything else, and a feeling described as a sinking away of the nerves. Both optic discs decidedly gray; otherwise no changes.

O. D. plus 1.75s \bigcirc plus .75c axis 15 $\frac{20}{90}$. O. S. plus 1.75s \bigcirc plus .50c axis 165 $\frac{20}{90}$. This and a suitable presbyopic correction, a month after its use caused the patient to report herself as doing well. It should be stated, however, that she was under careful general treatment and had undergone a prolonged rest-cure, and that any mental work was forbidden, or if it was undertaken was likely to produce a relapse.

Case 24. Fronto-occipital Headache; a Tendency to Fall Forward in Walking—A. J. Q., a woman aged 44, is in good general health with the exception of an acid dyspepsia and a great deal of general nervousness, probably induced by much sorrow in her family; cannot read or thread the needle, and has a good deal of fronto-occipital headache; the most aggravated feeling is that of falling forward when walking, probably a species of vertigo. In each eye an irregularly oval disc with a partially absorbed choroid ring. In the right eye some slight macular changes.

O. D. plus 3.5 plus .25c axis H $\frac{20}{90}$. O. S. plus 3.50s plus .50c axis H $\frac{20}{90}$. Her symptoms began to improve from the time the mydriatic was employed.

Of the twenty-four cases just detailed vertigo was a prominent symptom in eight of them, which was either relieved or cured in six by the use of the glasses, but unaffected in two. Ocular vertigo, usually subjective, is a common and constant symptom in errors of refraction, so much so that the investigation of a case is quite incomplete without a study of the eyes. It does not seem likely that it is any more common in cases of astigmatism against the rule than in those where the refraction error is according to the rule. In an analysis of one hundred cases of ordinary far-sighted astigmatism, I think it is not very unlikely that eight of them, at the very least, would complain among other symptoms, of attacks of vertigo. Cases 14 and 24, in which there was a confusion of ideas and the sensation of falling forward, especially when walking in a crowd, might also be classed among the vertigos. In this case the refraction error appears really to have been the cause of the disease. I have seen two precisely analogous cases alleviated by the correction of a refraction error, the one of an ordinary myopic astigmatism of low grade, the other of a simple hypermetropic astigmatism. The mere feeling of falling forward as a symptom in errors of refraction, in common with all of my colleagues, I have seen many times, but in the three cases detailed it was associated with a confusion of ideas and pallor of the cheeks of

such a grade that at the original examination *petit mal* was suspected. Three of the cases were associated with hypochondriasis or melancholia. In the melancholic cases there could be no possible connection traced between the error of focus and the mental state. In the other two cases the glasses appeared to be one of the factors which brought about relief, although both patients were under systematic general medication. All the cases of neurasthenia and general nervousness—it is difficult to secure another expression to describe their indescribable sensations—were relieved by the use of glasses, just as the relief of eye strain, the result of the more ordinary types of refraction error, will produce a like result; but general treatment was not lacking when indicated. In one of the cases of insomnia it was not possible to determine whether this was the result of the headache, of eye strain or of the pain of gout; more probably, however, the latter. Insomnia, either simple in character, or the result of night headache, which in its turn is caused by eye strain, is often indirectly relieved by the proper correcting lenses. In the woman who suffered from paræsthesia the effect of the glasses cannot be determined definitely because, in addition to their use, other measures of treatment were employed.

It seems from an examination of these cases that the associated symptoms, with perhaps several exceptions, were not more severe than would be present in a like number of cases of astigmatism according to the rule. It is very far from the purpose of this paper to belittle in any way the correction of all types of errors of refraction, for the purpose of improving ocular health, for relieving headache, and for removing a possible factor that may depress general nutrition and be a cause of a reflex neurosis. But it certainly seems to the writer that in the present day there is a tendency to ascribe too much effect from the correction of refraction errors, and that because these exist the search for other causes of the associated symptoms at times becomes defective. When astigmatism against the rule exists, as Dr. Theobald has said, "We are warranted in correcting fully every particle of the defect which we can render manifest," and which should thus be rendered by the judicious use of an active mydriatic. Perhaps in no other instance do we find the strikingly good effects of adding very weak cylinder to the combination of lenses; in a number of the instances detailed in this analysis the question of comfort or discomfort having been obtained by the finding or failing to find so low a degree as plus .25 D. The balance of the ocular muscles has not been recorded in the present series of cases, although it was studied carefully as a matter of routine practice. The presence or absence of insufficiency introduces an entirely different element, and its exact relation to reflex

troubles of various types at present is being weighed in the balance. It is almost hackneyed to repeat what, however, sometimes is forgotten, that apparent insufficiencies, especially of low degree, disappear entirely after full and proper corrections, and with their disappearance the associated symptoms subside. This, as Professor Knapp has said, is one of the most thankful tasks which the practicing ophthalmologist performs. No where is it more necessary that this full and careful correction should be obtained than in examples of astigmatism contrary to the rule associated with low grades of insufficiency.

In conclusion, from these one hundred cases of astigmatism contrary to the rule certain interesting facts may be ascertained.

Age. The following table represents the number of cases according to the age:

First decade.	2 cases.
Second "	9 "
Third "	5 "
Fourth "	14 "
Fifth "	25 "
Sixth "	26 "
Seventh "	17 "
Eighth "	2 "

It will be seen, then, that more than half the cases occurred between the ages of forty and sixty.

Sex.—The majority of the patients were women, thirty-one males, and sixty-nine females.

The Degree of Astigmatism.—This varied from a 0.12 of a dioptré to 2. dioptries; the vast majority of the cases representing low grades of astigmatism .50 to .90.

It may further be concluded:

1. That the associated symptoms in these cases of astigmatism were not more severe than probably would be found in a similar number of examples in which the refraction error was according to the rule.

2. That useful results follow the correction of the least degrees of measurable astigmatism—results which are not obtained when this correction is neglected, and that the mere presence of so-called normal central vision according to the ordinary best standards, does not preclude the possibility of low degrees of astigmatism being present, which should be sought out and corrected.

3. That ocular health is conserved by such careful and thorough measurements of astigmatism, and hence indirectly general or so called reflex disturbances are alleviated, but that these latter should never be ascribed solely to the astigmatism simply because this is present, when they may be the evident pointings of Nature for relief to be obtained by measures directed toward an insufficient constitutional vice or insufficient nervous tone.

4. That the importance of low degrees of insufficiencies of the ocular muscles should not be

estimated until the effect upon them of complete correction of the astigmatism has been obtained.

5. That while no doubt in careful hands excellent results may be obtained by ophthalmometry and skiascopy with prolonged mydriasis, the patient does not obtain the very benefit which is often most essential by the use of the mydriatic, namely, its local sedative influence and the complete rest which a prolonged paralysis of the ciliary muscle entails. The most perfect correction placed upon an eye the subject of symptomatic retino-choroidal disturbance, fails to fulfil its function until the former has been subdued, and in its subjection prolonged mydriasis plays an essential part.

DISCUSSION.

DR. S. M. BURNETT, Washington, thought that astigmatism contrary to the rule was more productive of painful eye symptoms than when it was according to the rule. He had never been able to find a satisfactory explanation of this, but he has found that 0.5 D of astigmatism contrary to the rule will generally cause more trouble than 1. D of astigmatism according to the rule.

DR. SAVAGE explained his theories of asthenopia in astigmatism in which the meridians deviate from the vertical or horizontal position. This is especially the case if there is asymmetry between the meridians of the two eyes. He illustrated how this asthenopia is produced by the oblique muscles rotating the eye on their antero-posterior axis in their endeavor to make an oblique meridian correspond to a vertical or horizontal one.

DR. JACKSON said he had observed no further trouble from astigmatism against the rule than with the rule.

FUGITIVE BLOOD CORPUSCLES IN A CASE OF LYMPHADENOMA.

BY J. H. WYTHE, M.D., LL.D., F.R.M.S.,
OF SAN FRANCISCO.

Microscopic examination of a drop of blood from the finger of a patient with lymphadenoma of long standing, revealed several interesting phenomena. The examination was made with a B. and L. homogeneous immersion objective, N. A. 1.43, and Zeiss' compensating eye-pieces, giving a magnifying power of 800 to 2,400 diameters. Lower powers are of little use in examining blood corpuscles. The drop of blood was placed upon a thin cover-glass, which was quickly dropped upon a slide and gentle pressure made upon it, so as to obtain a thin layer.

A little more than a year ago, in an essay read before the California State Medical Society, and published in its Transactions, I reported my observation upon the structure of normal blood

corpuscles, as seen in a solution of bichromate of potass. These observations showed a great difference in size, shape and activity among the corpuscles, corresponding, in all probability, to a variety of functions. Alterations of shape and structure were also seen, which were referred to post-mortem disintegration. The albuminoid hæmoglobin was seen to ooze out of the matrix of the red corpuscle, to move about the field of view with amœboid motions, and to break up into smaller masses, which again subdivided into granules. Many of these changes were seen also in the specimen referred to in the present paper, although no reagent whatever was employed, proving satisfactorily that the appearances were not artificial products.

As might have been anticipated in a case of lymphadenoma, the white corpuscles were quite numerous. They were at first round or globular, and slightly larger than the average red discs, but in a little while began to swell and became an irregularly shaped network of convoluted fibres. The red corpuscles varied in size, some being about half the diameters of others. They were generally discoid, but of irregular contour, and gradually becoming more distorted. Some of them were considerably elongated and even branched, while others retained a more or less circular outline. Projections, or knobs, appeared as if growing on a majority of the discs, and were sharply defined in the field of view.

In addition to the red and white corpuscles, numerous bright, shining particles, or microcytes, were visible, some of which seemed to be nuclei of partially dissolved cells.

The first observations were made in the forenoon, but on account of professional duties the microscope, with the slide focussed on the stage, was covered with a bell-glass and allowed to remain until evening, when it was found that nearly all the corpuscles, both white and red, had disappeared, leaving only a slight stain of hæmoglobin. Many of the shining microcytes still remained. The attention of Dr. Fisher was called to the phenomenon, as well as to the paleness of the few remaining red corpuscles, which in an hour more had all disappeared, except a few which had dried at the edge of the specimen.

Since the announcement by Dr. Prudden of the germicidal power of the blood serum, several European observers have made confirmatory statements, so that there is little doubt of the power of the lymph, or serum, to dissolve bacteria. May not this property account for the disappearance of the blood-corpuscles in lymphoid disease? If the shining nuclei be remnants of cells dissolved by the fluid lymph, it would seem that they are more resistant to its phagocytic power than the red and white corpuscles. These considerations emphasize the importance of investigating the vital changes occurring in the

white blood, or fluid circulating through the entire lymphatic and vascular system, and which, from its more general presence, must be of greater physiological and pathological importance than the corpuscles of the blood.

The cellular pathology inaugurated by the illustrious Virchow has had a brilliant history, and has added greatly to our knowledge, but recent microscopic research indicates the necessity of revision and change of statement relative to elementary biology. We can no longer regard the first living mass of matter as a cell, and the nucleus and nucleolus is not considered as important as formerly, while the tendency to the formation of living fibres in specialized networks is seen to be an elementary principle. It may be in the near future that we shall regard the white blood of any organized body as "the life thereof."

The patient referred to was ordered fifteen drops of syr. ferri et manganese iodidi in 3i of syr. of hydriodic acid, three times a day, and in a month's time there was evident reduction in the size of the tumor. The blood was again examined as nearly as possible under the same circumstances as before. The same diversities of size and appearance were observed in the red corpuscles. The white cells showed the same convoluted fibres, but in an hour's time disappeared. About three-fourths of the red discs became knobbed, irregular, or broke up into smaller globules, while the rest retained their circular outline. Many of them, in groups of two to five, became fused together into irregular masses. The most careful focussing, with varied obliquity of light, failed to find any line of demarkation between the corpuscles.

A much smaller number of the bright shining particles, or nuclei, were seen in the later specimen.

It was quite evident that the treatment had strengthened the resisting power of the red corpuscles, and they were not dissolved, and had reduced the number of separate bright nuclei.

TONSILLOTOMY.—We are justified in drawing the following conclusions:

1. That the only reported case of fatal hæmorrhage needs further corroboration before it should influence the usefulness of tonsillotomy.
2. That age is of all other conditions the most prolific cause of hæmorrhage.
3. That the early removal—that is, before the tonsillar tissue has become hard and fibrous—will reduce the probability of an alarming hæmorrhage to the ratio of one to all the reported cases of tonsillotomy.
4. That if the operation is skilfully performed with a tonsillotome, and the throat subsequently properly cared for, the probabilities of even a slight hæmorrhage are very small.—Fitzpatrick, *Lancet-Clinic*.

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, SEPTEMBER 3, 1891.

EPIDEMIC TYPHOID FEVER AT WATERBURY,
CONNECTICUT.

The last annual report of the Connecticut Board of Health, a volume of over 300 pages, just published, contains the history of an epidemic of typhoid fever in Waterbury, occurring in the midsummer of 1890. The special paper in the report, tracing the outbreak to "dairy typhoid," or to infection by typhoid-impregnated milk, was written by DR. HERBERT E. SMITH, professor of chemistry in Yale Medical College. DR. SMITH was detailed to investigate a sudden outburst of fever in June, 1890, of about fifty cases in a period of twenty-three days, limited to thirty-five families within the town. Not much success has, in this country, attended investigations intended to prove the relations of milk to typhoid fever; but in this instance we are presented with proofs of these relations that appear to be irrefutable. Although milk-typhoid has undoubtedly occurred in this country more frequently than has been generally known, there have been not a few unexplained epidemics of fever, whereof the chains of conditions and surroundings have been suspiciously similar to those discovered at Waterbury and at the Middlebury farm, whence the alleged infected milk was derived for the use of the families residing in one section of the town. The distinctly proven cases of milk-ty-

phoid have been, in other countries, sufficiently frequent and destructive to show that it is a reality and a dangerous foe to human health and life. In 1881, MR. ERNEST HART, the well-known editor of the *British Medical Journal*, and of the *London Sanitary Record*, read a paper before the International Medical Congress, in which he gave a brief account of not less than fifty outbreaks of fever, embracing over three thousand cases, that were caused by milk-infection. These epidemics had been the subjects of persistent and thorough investigation during a period of eight years or more prior to MR. HART'S report. The greater number of these fifty epidemics were in England, and had been officially recognized and acknowledged. Since that time other cases of milk-infection have been reported, but their gravity has been materially subdued by sanitary precautions. The dairies of England have, in late years, been placed under a vigilant inspection, so that errors of construction about dairies, and dangerous practices on the part of dairymen, have been reduced to a minimum. In the present case of the Waterbury outbreak, the investigator made some few inquiries regarding its possible causation by the water supply and drainage system of the parts of the town affected, but his results were negative. In regard to the milk supply the reverse was the result, for he early found significant hints of an infected dairy, which were abundantly confirmed as his inquiry progressed. As a starting-point, DR. SMITH felt that he had to contend with a far reaching method of infection, for the reason that June is not one of the typhoid months, so to speak; in that region the most usual time for the appearance of cases of fever is in the early fall. He found that a certain dealer in milk supplied four-fifths of the families, living in two-thirds of the houses, where the disease occurred. This dealer probably served not more than 4 per cent. of the townspeople, with daily deliveries amounting to 600 quarts. His milk was obtained chiefly from three farms, concerning two of which there was absolutely no typhoidal history. One farm, however, had had not less than three cases of fever, and this was a source of one-quarter of the dealer's daily supply. It is probable that the milk from this dairy was contaminated both aerially and through the water used for the washing of cans. The sources of water on the farm were not in good sanitary condition, but a

bacteriological examination, made late in the month, did not discover the specific bacillus of EBERTH; the cow-yard and the milk-room presented conditions that were in several particulars favorable to the dissemination of infecting material or media.

At the time of DR. SMITH'S visits to the farm, he found the barn-yard very offensive from an accumulation of manure, which had not been removed for several weeks, owing to the farmer's illness, during that time, by typhoid fever; the yard was undrained and so situated as to hold ponded filth, several inches in depth, at its most depressed portions. The investigation failed to detect any gross contamination of the milk—the inquiry was begun too late to render this discovery probable—and it is not to be considered necessary to the making out of a strong anti-dairy argument, for as Dr. SMITH points out, it has been repeatedly shown that the specific contagium of typhoid fever, excreted in the stools, has ample powers of self-multiplication; and further, as WOLFHÜGEL, SEITZ and HEIM have demonstrated more recently, the article milk, whether sterilized or unsterilized, becomes an excellent culture medium for the bacillus typhosus. And it has been still further shown that, with a temperature not exceeding 55° F., the bacillus grows quite readily, and this was the temperature that was noted in the milk-room where the cans stood before leaving the dairy-farm. A pure water supply, above suspicion and amply protected from every form of sewage contamination, is a desideratum of the first moment, from the fact that the water used in cleansing the cans and other appurtenances is probably the readiest means of bringing the contagium from infected excreta into contact with the milk. Motives of policy, as well as humanity, alike point to the importance of having the purity of the milk and the cleanliness of all vessels, used in its preparation and transportation to the consumer, made as complete and perfect as possible. And it should be especially remembered in this connection that something more than an apparently pure water is required, for we may have a contaminated supply, even from sources of gross excrementitious pollution, without its yielding any evidence of impurity to our senses. It is further held by experts that, in the bacteriological study of milk and of water, it is not always possible to detect

the EBERTH'S bacillus, when a certain time has elapsed after the febrile outburst. Excrementitious contamination may be found at a late date, but to give the investigator the fullest and best opportunity for identifying the bacillus he should be called into the examination at the earliest practicable period of time. The author of the report closes with a special admonition as to the position of cesspools, privies, etc., on dairy farms, saying that they "should be properly located, properly constructed, properly cared for, and their proper use should be insisted on, because of the direct dangers of the contamination of the milk by those whose duty it is to take care of it." The ordinary conduct of the majority of our dairy-farms ignores all probability, if not possibility, of domestic pollution, and a lesson might be read to dairymen, from the Waterbury incident, to show that three cases of fever, one of them fatal, may arise upon the dairy-farm itself concurrently with the fifty cases or more which visited the townspeople. The typhoidal dairy is dangerous to its own residents not less than to its customers.

THE PASTEUR TREATMENT OF HYDROPHOBIA.

Among the many interesting and valuable papers presented at the Seventh International Congress of Hygiene and Demography recently held in London, the one, presented by Dr. E. ROUX, one of PASTEUR'S principal co-workers, deserves special mention.

PASTEUR'S treatment of hydrophobia consists in producing, during the period of incubation of the disease, an artificial immunity in the person bitten by a rabid animal. This is accomplished by inoculating the individual on successive days with virus of different degrees of activity, commencing with a very attenuated virus and using on each succeeding day a virus of greater intensity.

The virus is obtained in the following manner: With the most complete antiseptic precautions, a rabbit is trephined at the back of the skull, and a few drops of the cerebro-spinal fluid of an animal suffering from rabies is injected under the dura mater. The piece of bone removed is then returned and the wound closed up. The wound heals rapidly and after a certain length of time, a week, the animal sickens and in three days more

dies of distinct hydrophobia. The cerebro-spinal fluid is used for inoculation in preference to any other fluid of the mad animal, because no other poison than that of hydrophobia produces such effects. Immediately after the death of the animal the spinal cord is removed with antiseptic precautions, and suspended in an aseptic flask containing some solid caustic potash, whose hygroscopic properties enable it to dry the air of the flask. When first removed the cord contains a virus of high but constant virulence, but gradually loses this virulence during the drying process, and in 15 days the poison has completely disappeared. The cord is rubbed up with sterilized bouillon to make an emulsion of definite strength, and this emulsion is used for the inoculations of human beings. The virus of the 14 day cord, that is, the cord which has dried 14 days, is so weak that it can be injected without danger into the human subject, but it produces a certain degree of immunity and prepares that subject to receive the injection of the cord of 13 days. Each succeeding injection of a stronger virus increases the immunity of the individual until finally complete immunity is conferred. If this complete immunity is conferred before the virus introduced by the bite of the rabid animal has had time to develop, the patient is prevented from having hydrophobia. The details of the method will be better understood from the following table, which gives the plan followed at the Pasteur Institute in cases of ordinary bites. The table is well known, having been frequently published, but its consideration here will certainly not be without interest.

1st day—cord of	{ 14 days, dose 3 c.c. of emulsion.

In cases of bites about the head, the period of incubation is often very short, so that it becomes

necessary to hurry the treatment, particularly during the earlier days. During the first two days four injections are given daily instead of two. In addition the treatment is continued longer.

The cases treated at the Pasteur Institute are divisible into three classes: first, those bitten by animals recognized by subsequent experiment to be suffering from rabies; second, those bitten by animals recognized by veterinary surgeons, to be rabid; and third, those bitten by animals suspected to be rabid. Throwing out the latter class altogether, still remain in the first two classes, 7,925 cases treated during the five years ending Dec. 31, 1890. DR. ROUX did not include the cases treated during the current year in his statistics because of the short time which has elapsed since their treatment. The number treated is sufficiently large to make conclusions based upon them of some value. It is impossible to say how many of the cases treated by PASTEUR would have escaped if they had not undergone his treatment, but it is known that the mortality among persons bitten by animals actually or presumably rabid, is 12 to 14 per cent., and it is fair to suppose that the mortality among PASTEUR'S cases of the same type would not have differed materially, particularly when the large number of the cases is considered. But the mortality among PASTEUR'S first two classes of cases was less than 1 per cent., the exact figure being 0.92 per cent.

The gravity of bites about the head is well known, the mortality in cases not treated being 80 per cent. Seven hundred and ten persons bitten about the head have been treated at the Pasteur Institute, and twenty-four have died, a mortality of only 3.38 per cent.

From such a showing it is impossible to avoid the conclusion that the treatment has been effective to a large degree. DR. ROUX asks, what one among all the methods of treatment known to medicine could claim to have fewer failures?

Have PASTEUR'S detractors anything better to propose?

Most of the deaths among the persons treated, occurred within two weeks after the cessation of treatment, which shows that the disease had already commenced before treatment was begun.

In another class of cases the period of incubation is very long, the disease not developing until

months or years after the reception of the bite. In these cases the PASTEUR treatment may fail, because the immunity conferred by it is lost before the hydrophobia develops.

Great as has been the good accomplished by PASTEUR in treatment of hydrophobia, his greatest honor lies in the possibility which he has opened up of preventing other infectious diseases by conferring an artificial immunity. His glory is as great as that of JENNER.

THE SO-CALLED BICHLORIDE OF GOLD TREATMENT FOR INEBRIETY.

This subject was discussed at the Practitioners' Club of Chicago during the current week. A great diversity of opinion was found among the members upon the subject. Quite a number of the members referred to confirmed inebriates of their acquaintance who had been relieved of their infirmity at Dwight. As to the permanence of the cures effected, no one could express an opinion. One gentleman, whose professional duties brought him much in relation with inebriates, told of several cases of a return of the habit in individuals who had been apparently cured at Dwight.

The red cinchona cure for drunkenness was recalled. This plan of treatment had been loudly extolled by the daily press at the time that it was in vogue, and the same extravagant claims made for it, as are now being made for the so-called bichloride of gold treatment. And yet this plan is now practically abandoned, because found wanting.

As to the therapeutic measures employed at Dwight, it was the general belief that the remedies employed were strychnia and atropine, remedies long known to the profession as possessing a certain degree of usefulness in inebriety. It has not been shown that gold in any shape plays any rôle in the treatment, except as "coin of the realm" poured into the coffers at Dwight.

How then can the good results which are unquestionably obtained at Dwight be accounted for? In the first place, the patients are selected cases. They go with the desire to overcome their habit or disease, whichever it may be called; they are constantly under observation, the slightest infraction of the rules of the place is met with prompt dismissal, all the surroundings bear most

strongly in the right direction upon the patient, and the psychic element thus invoked is unquestionably the strongest factor in the cure. If now to this be added the well-known beneficial effects of such remedies as atropine and strychnia, it is quite likely that cures may be produced. But temporary cures are of little value, permanent cures are needed, and here come in the "Bichloride of Gold" clubs, whose influence in maintaining sobriety in the graduates of Dwight can not be overestimated.

For the good that is accomplished at Dwight we have nothing but words of praise; there is no honorable man but is gratified at the reclamation of a drunkard. All honor to the Bichloride of Gold clubs, for they are working in good faith. Can we say as much for the institution at Dwight? We have been informed by the late Secretary of the State Board of Health, that the manager of this institution was refused a license to practice medicine in Illinois.

It has been the experience of the profession that secret remedies are not used in good faith, and lose their efficacy when exposed to light. It seems impossible for the laity, and particularly the public press, to understand the position taken by the profession on secret remedies. No true physician will withhold from his fellows any discovery which he may make that will benefit humanity. To enjoy a monopoly, for financial purposes, is entirely foreign to the spirit of the medical profession, and is never tolerated by it. It invariably purges itself of members guilty of such acts. If the treatment at Dwight be what is claimed for it, it should be freely taught to the world, as the number of cases of inebriety which can be treated at the Dwight institute and its branches, is but a trifling percentage of the cases in the country, in the world. Let the laity compare the action of a secret holder of a remedy with the nobility of Pasteur, whose work on hydrophobia is considered editorially in this issue, and they will appreciate better perhaps, the professional objection to secrecy.

If the originator of this treatment will demonstrate to the profession that he can accomplish what he claims, honors without stint will be accorded him, and his finances would certainly suffer no diminution. But if the efficacy of his treatment depends entirely upon secrecy, it will certainly not be made public, and the world must content itself with the limited efforts of the institution at Dwight.

THE PRACTITIONERS' CLUB OF CHICAGO.

Last Monday evening the first meeting of this organization was held in the Palmer House. The number of gentlemen who answered the call of assembly was an even half hundred. The enjoyment and enthusiasm of the occasion was an omen of assured success. The purpose of the club was fitly designated as: A monthly gathering—a good dinner, reasonable hours, nominal expense, good fellowship, light discussions, no officers, a closer professional feeling.

Such comings together of men of kindred minds and pursuits, with laudable purposes, are always fraught with good. We are sure that every town or city with more than a dozen doctors in it should have such a club as this. In such meetings may be discussed a variety of themes which are not usually taken up in more formal society meetings, such as the relations of the medical profession to the public, and of the public to the medical profession; the furtherance of all interests pertaining to the common welfare both of the people and of the profession. At such meetings, with agreeable surroundings and face to face, united action, harmoniously brought about, is much more easily and better obtained than when acting separately, although for the same purpose. Besides, we all think better and more kindly of each other for having once a month sat with our nether limbs under the same mahogany, walnut or oak table.

The members of the medical profession in every city of a hundred thousand people should have their own home. They may be only able to rent a humble dwelling for such a purpose, but by all means rent until able to own, and there have a library, a reading and common sitting room, a dining room and kitchen. A fraternal spirit and union of hearts will there be knit together. Professional homes are promoters of peace and goodwill, and from them are sure to spring the benevolent sentiment that encourages the strong to care for and not step aside to crush out the life of the weak and perhaps unfortunate. In the cultivation of this spirit and sentiment strong men are made stronger, and their lives more loveable. Their angular points are smoothed down until they are so polished as to on all occasions reflect the nobleness of soul that is within them, while the weak but deserving are held up and encouraged in practical ways.

A home is needed to bring about such desirable results. Once obtained, foster it with gifts as you would show your affection for a much loved child. Carry to it a book for its shelves, or the shelves to hold another man's book, a picture, a journal. The home may be a trysting place in which to leave a call for another to make.

The Practitioners' Club of Chicago and every similar organization needs a home and needs it badly.

"*IODOFORM DRACHMS TEN.*"—Dr. Edward Jackson, in the *Medical News*, treats of the difficulties he has experienced in weighing the testimonies of those who report exceptionally favorable results from certain special lines of treatment for immature cataract. He has been troubled by the "too rosy" reports of cases, which assert too much and give too little proof to satisfy the minds of others. He says he is reminded, by these illogical displays, of a recent paper read before a homœopathic society, narrating five cases—one of them in the person of an allopathic physician—in which great improvement took place after the use of "iodoform 5x." This is probably the foggiest therapeutic statement that has been seen by any of our readers within the past decade. To us it is painfully suggestive of an admixture of ignorance, incompetence and impudence, in equal parts.

AN OBSTETRICIAN'S GENEROUS OFFER.—The eminent French professor of obstetrics, Dr. Tarnier, does not forget the lowly village where he was born, named Arc-sur-Fille. He has observed with grief the diminishing natality of his nation, and has determined to give a practical expression to this feeling in a novel manner: he has promised a gift of one hundred francs to every family at Arc-sur-Fille which shall have contributed an infant to the population of France during the year 1892. This is an original way of causing married people to reflect on one branch of their duties in life, but the villages in question can have no reason to complain that they have not received a timely warning.

A PRINCELY GIFT.—The King of Italy recently celebrated a birthday and did himself no small honor by sending a munificent contribution to the city of Turin, which is just now struggling to raise a fund for the erection of a hospital for contagious diseases. His gift is quoted at \$160,000 lire, or about \$32,000.

FOREIGN CORRESPONDENCE.

LETTER FROM VIENNA.

During the latter part of the present century, Vienna has become one of the greatest, if not the greatest, medical centre of Continental Europe. Hence, the whole medical world naturally looks to that city for the latest, as well as the most useful revelations in medical science, in all the various specialties, for many of them are diligently cultivated in the Austrian capital; and one will notice here, as in Berlin and Dresden, that many practitioners announce their special line of practice by large gilded signs, conspicuously placed over their doors.

That this should be a great teaching centre for those having a speaking knowledge of German, one can easily comprehend; because its professors in the hospitals are mostly men of worldwide reputations, many of whom are well known as authors and operators. Besides, their great, colossal hospital, on the *Aller Strasse*, being practically the only general hospital for the city, with its million and a quarter of population, along with its numerous suburban districts, clinical material is massed there, and there are shoals of material for every conceivable specialty.

This immense hospital and its grounds cover at least ten acres. It is constructed on the same architectural plans as are all the principal public buildings here; their courts, museums and military barracks, *i. e.*, the group takes the form of a quadrangle, with a large court, or hollow square, of open space in the centre, with many walks handsomely soddled, and all sheltered by numerous large shade trees.

In Professors Billroth and Albert's departments, surgical clinics are held every morning, often commencing as early as 7 or half an hour later, in the morning. These large surgical wards are well filled with many interesting cases. Professor Billroth is one of those who have great faith in the efficacy of the radical operation for the cure of reducible hernia; and among the many cases which I saw in his spacious wards, which were treated for radical cure was one man of 50 years, who had two herniæ operated on simultaneously. The method lately employed by the eminent professor is Bassini's, of Padua. It is claimed for it, that its results are the most satisfactory and desirable; while on the other hand, not infrequently, in spite of every precaution, suppuration ensues in the wound, and often there is no inconsiderable sloughing of the aponeurotic, fibrous tissues.

In Professor Albert's service, hospital and ambulant, the radical operation is seldom undertaken, except in those cases of painful incarceration, or impending strangulation.

It is interesting here to note the difference in technique of operation, in the practice of these two distinguished teachers in the same hospital. With Prof. Billroth, the irrigator is almost never employed, main reliance being placed on vigorous asepsis, the free use of soapsuds, and the sterilizing oven.

With the one, all the assistants must wear heavy rubber clogs and rubber aprons to save themselves from a free

wetting, while with the other, their morning, polished calf boots are worn all through, and, with the exception of being now and then smeared with blood, are none the worse for it.

In one particular, however, they both agree; neither uses sponges of any description in ordinary operations, but depend wholly on pledgets of cotton or gauze, for wiping away effused blood.

A material called, I believe, "wood wool," is employed in Billroth's clinic, in its loose state, for scrubbing purposes. If made from hard, tough wood, a small handful of it, wetted and lathered, can be used much more expeditiously than any sort of brush ever devised. After being employed it is thrown aside. In its dry state, when cut fine, it makes an excellent felting or padding, and serves the triple purpose of support, protection from cold, and lastly, being as porous as a sponge, is unrivaled as an absorbent.

The use of Koch's lymph for surgical tuberculosis has been abandoned entirely in this institution, as also, I am informed, it has been pretty generally throughout Austria. This is very greatly to be regretted, for tuberculous disease seems to be the scourge of Germany. I was informed that, taking all the surgical cases together, young and old, fully 80 per cent. were in one way or another complicated with this disease; and indeed, from the great number of hunchbacks and cripples seen in the cities of this section, there can be little doubt that the truth has not been overstated.

Cocaine anaesthesia, as a local analgesic, is being largely employed here, for those operations in which no large nerve trunks are being divided, or bones cut through. Without question, when cocaine is applied skilfully, and its powerful analgesic properties are understood, it will be more largely employed, both to the advantage of the patient and the operator.

Iodoform gauze still holds its own, although one does not see the dry drug peppered over denuded surfaces, as was the custom in America—and I suppose among the Teutons—not long since.

It may be interesting to inquire what the great advantages of these hospitals in Continental Europe are, that Americans should pass by their own great cities, where every possible facility is given by eminent teachers, in the various post-graduate schools and hospitals, to enter cities, of the language of which many of them know nothing.

It may be said in reply, that travel broadens and develops the mind, and that these older countries are better equipped than ours for imparting an education, medical as well as any other; that their term of study is so much longer, etc. This latter has been particularly harped on lately, in America, by some who would extend the term of study so long that, when a student got through, he would be pretty sure to know nothing. And besides, for this precious privilege few but the sons of millionaires could compete. Dr. Lauder Brunton argued, at the late meeting of the British Medical Association, for an extension of the term of study, but failed, I believe, in convincing his audience on this point.

As a matter of fact, our system of teaching medicine in

America is excelled by no nation in Europe. When our young men enter a medical school, it is not for the purpose of idling away three or four years in doing little or nothing; then, as the time for the final "rub" comes, employing a skilled "grind" to get them in form for the race, the examination. Our principal hospitals have everything that can be had in the way of teaching. Hence, unless one is engaged in a special line of study, and has plenty of spare cash and leisure, let him first avail himself of the home opportunities, before he meditates a trip to Europe.

THOMAS H. MANLEY, M.D.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Although the profession may not be in entire accord as to the practical contagiousness of leprosy, there can be little question of the propriety of the action of the health authorities in isolating in a hospital tent on North Brothers Island the two Chinese lepers recently discovered in this city. What the final disposition of the patients may be is as yet somewhat uncertain, but it seems probable that they will eventually be returned to their native country. One of them is said to be possessed of ample means, and the United States Government may perhaps provide for the return of the other.

The action referred to was taken in accordance with the suggestions made in a special report upon the subject presented by Dr. Cyrus Edson, Chief of the Bureau of Contagious Disease. In this report Dr. Edson refers to the fact that numerous competent medical observers assert that under certain conditions leprosy is contagious. Among these he mentions Dr. R. Arment Hansen, the discoverer of the bacillus lepræ, Sir Morrell MacKenzie, Dr. Van Dyke Carter, Dr. N. C. Macnamara, and a number of American dermatologists. He then goes on to say: "The conditions favorable to the spread of leprosy are those existing in the so-called Chinese quarter in this city. Here we have a population consisting of people who are admitted by all authorities to be susceptible to the disease, among whom it is prevalent, and by whom many claim that it has been introduced into countries previously free from leprosy, as, for example, the Sandwich Islands and Australia. The habits of life as practiced by the Chinese in their so-called quarter are such as tend to favor the spread of any disease of a contagious nature. It is not necessary, in my opinion, to consider the anti-contagionist theory of leprosy. This theory is honestly maintained by such men as Danielson, of Norway, Nelson, of Canada, and others.

"Dr. C. M. Allen, in an introductory note to the well-known paper by Dr. MacKenzie, entitled, 'The Dreadful Revival of Leprosy,' very aptly says in regard to the opinion of the anti-contagionists, 'Honest opinion is always to be respected, but how many men of recognized ability in the profession who are fully cognizant of the history of the disease can believe it safe or wise to ad-

mit lepers into our country and harbor them here, where the chances of escaping the scourge are so great if proper precautions are taken, is beyond my comprehension.'

"Personally, I have given my opinion in regard to the contagion of leprosy in a recent paper. I believe leprosy to be contagious under certain conditions. These conditions, in my opinion, as I have before stated, exist in this city in the Chinese quarter. Between the honest differences of opinion that exist upon the subject of contagion, a large element of doubt, to say the least, is created. The benefit of this doubt should be given the people, to conserve public health. I therefore respectfully recommend that the two lepers in question be taken in charge by this department until they can be properly cared for by some other means. I also respectfully recommend that steps be taken at once to bring the matter of the care of leprosy before the United States authorities, to the end that a National lazaretto, where leprosy cases can be isolated, be established on the Atlantic coast."

In commenting on the disposal of these cases the President of the Board of Health, Mr. Wilson, remarked that the action of the Board was taken on consultation with the best physicians in the city, and that the members of the Board believed from the testimony submitted, that the isolation of the lepers was a necessary public measure. He also expressed the opinion that should a legal test be made, the courts would sustain this view.

The bodies sent to the city morgue do not often come to life, but this was the case in the instance of an apparently still-born infant brought there by its father a short time since. The child was a premature one, measuring but nine inches in length, and weighing but a pound and three-quarters, and as it showed no signs of life when born the ignorant midwife in attendance did not think it worth while to take any measures to resuscitate it, and told the father that the right thing to do with it was to take it to the morgue. Soon after the body of the infant had been laid upon the cold, hard slab it began to revive and uttered a feeble cry. The astonished keeper of the morgue snatched it up, and, wrapping a cloth about it rushed with it to Bellevue Hospital, near-by, where it was promptly treated with all possible care. Unfortunately, however, the little stranger was not long for this world, and a day or two afterward it died in earnest. Possibly, if the child had received proper treatment at the time of its birth—the exposure to which it was afterwards subjected thus having been avoided—it might perhaps have survived and eventually grown up to be a useful member of society. This is only one of the far too numerous cases of neglect and incompetence on the part of midwives that are continually occurring, and there can be no question that there is urgent need of reform in the matter of granting licenses to this class of persons. At present almost any woman, however ignorant, can apply for and obtain a certificate authorizing her to practice midwifery.

A Mrs. Charlotte Smith recently celebrated her hundred and first birthday at the residence of a daughter in Brooklyn, and in honor of the event she was waited upon by a large number of descendants, the youngest of whom

is a great-great-grandchild. The worthy old lady, who still retains her faculties in a remarkable degree, has now living six sons and daughters, thirty-four grandchildren, thirty-one great-grandchildren, and eighteen great-great-grand-children.

On the same day as Mrs. Smith, the newspapers report "Aunt Betsey Saunders," an inmate of the almshouse at Norwalk, Conn., was 101 years old, and the selectmen of the town, assisted by the inmates of the institution, properly celebrated the event. A substantial and more or less elaborate dinner was served, with the centenarian sitting in the place of honor at the head of the table.

While upon the subject of longevity it is worth while to mention that one day in August there was reported at the Bureau of Vital Statistics, the death of a negro, an inmate of the Colored Home of this city, at the remarkable age of 116 years. It is said that his wife, who died in November, 1888, at Astoria, just across the East River, where the old couple had lived in a small cabin for a very long time, attained the age of 110 years. P. B. P.

The Congress of American Physicians and Surgeons.

SECOND TRIENNIAL SESSION.

The Congress meets in Washington, D.C., September 22, to 25, inclusive. It is composed of the members of those National Medical Societies whose names and Secretaries are given below, and of foreign guests specially invited by the Executive Committee.

To enable a physician residing in the United States to become a member of the Congress, with the right to participate in its proceedings, it is necessary that he be a member of one of these Constituent National Societies.

A physician may be accredited as a visitor to the Congress by any one of the Constituent Societies. The certificate of the Secretary of one of these societies to the effect that he is thus accredited will enable him to register upon payment of the registration fee, which registration will entitle him to a card of admission to the President's reception and to a copy of the Transactions of the Congress, but not to take part in the deliberations of the Congress.

The following are the names of the Constituent Societies in the order of date of their organization, and the names and addresses of their respective Secretaries, to whom inquiries, as to mode of obtaining membership, should be addressed:

American Ophthalmological Society, Secretary, S. B. St. John, M.D., Hartford, Conn.

American Otological Society, Secretary, J. J. B. Vermyne, M.D., New Bedford, Mass.

American Neurological Association, Secretary, Graeme M. Hammond, M.D., 55 W. 46th Street, New York City.

American Gynecological Society, Secretary, H. C. Coe, M.D., 27 E. 64th Street, N. Y. City.

American Dermatological Association, Secretary, Geo. Thomas Jackson, M.D., 14 E. 31st Street, N. Y. City.

American Laryngological Association, Secretary, Chas. H. Knight, M.D., 20 W. 31st Street, New York City.

American Surgical Association, Secretary, J. R. Weist, M.D., 118 N. 8th Street, Richmond, Ind.

American Climatological Society, Secretary, J. B. Walker, M.D., 1617 Green Street, Philadelphia, Pa.

Association of American Physicians, Secretary, Henry Hun, M.D., 33 Elk Street, Albany, N. Y.

American Association of Andrology and Syphilology, Secretary, J. A. Fordyce, M.D., 66 Park Ave. N. Y. City.

American Orthopaedic Association, Secretary, John Ridlon, M.D., 337 W. 57th Street, N. Y. City.

American Physiological Society, Secretary, H. Newell Martin, M.D., Baltimore, Md.

Association of American Anatomists, Secretary, D. S. Lamb, M.D., 800 10th Street, Washington, D. C.

American Pediatric Society, Secretary, W. D. Booker, M.D., 851 Park Ave., Baltimore, Md.

All physicians are invited to attend the meetings of the Congress and the public meetings of the Societies, but only those may register who are members, specially invited guests, or visitors accredited through the Secretaries of Constituent Societies.

The registration office will be in parlors 1 and 2 of the Arlington Hotel. From this office the mail of members and invited guests will be distributed, and here the city address of each member, guest, and accredited visitor can be ascertained. All members, invited guests and accredited visitors should register as soon as possible.

A registration fee of five dollars will be required of all members and accredited visitors. Invited foreign guests will register, but will pay no registration fee. A copy of the published Transactions of the Congress will be sent to all members, and to each invited guest and accredited visitor who is registered.

Only those who register, and the ladies accompanying them, will be admitted to the reception of the President of the Congress.

It is recommended that members effect registration in advance of the meeting by filling out the blank certificates of registration which will be sent to each member about September 10, and forwarding these certificates, with the requisite fee, to Dr. John S. Billings, Treasurer of the Congress.

The sessions of the Congress will be held from 3 to 6 P.M., daily, in the Main Hall of the Grand Army Buildings, 1412 and 1414 Pennsylvania Avenue.

The sessions of the Societies will be held according to the programs of each, as follows:

American Ophthalmological Society, Ladies Parlor, No 2, Arlington Hotel.

American Otological Society, Ladies Parlor, No 1, Arlington Hotel.

American Neurological Association, Parlors 182 and 183, Arlington Hotel.

American Gynecological Society, Lecture Hall, Columbian University, Cor. 15th and H Sts. N. W.

American Dermatological Association, Parlor, The Shoreham.

American Laryngological Association, Parlor A., Arlington Hotel.

American Surgical Association, Main Hall, Grand Army Building, 1412 and 1414 Pa. Ave.

American Climatological Association, Hall No. 2, Grand Army Building, 1412 and 1414 Pa. Ave.

Association of American Physicians, Hall No. 1, Grand Army Building, 1412 and 1414 Pa. Ave.

American Association of Andrology and Syphilology, The Shoreham.

American Orthopædic Association, New Reception Room, Arlington Hotel.

American Physiological Society, Parlor 181, Arlington Hotel.

Association of American Anatomists, Hall No. 3, Grand Army Building, 1412 and 1414 Pa. Ave.

American Pediatric Society, Parlor 206, Arlington Hotel.

The President of the Congress, Dr. S. Weir Mitchell, of Philadelphia, will deliver an address Wednesday evening, September 23, at 8 P.M., "On the History of Instrumental Precision in Medicine."

Members of the American Surgical Association and of the Association of American Physicians will conjointly entertain their foreign guests at a dinner at the Arlington Hotel, Thursday, September 24, at 8 P.M.

The American Gynecological Society will give a dinner at the Arlington Hotel, Thursday evening, September 24.

The American Orthopædic Association will give a dinner at the Hotel Arno, Thursday evening, September 24.

The American Laryngological Association will give a dinner at the Hotel Arno, Thursday, September 24, at 7 P.M.

The American Pediatric Society will give a dinner at the Arlington Hotel, Thursday evening, September 24.

The American Dermatological Association and the American Association of Andrology and Syphilology will, conjointly, give a dinner Tuesday evening, September 22.

The American Neurological Association will give a dinner at the Hotel Arno, Thursday evening, September 24.

The American Climatological Association will give a dinner, the time and place to be announced hereafter.

A number of distinguished physicians and surgeons from abroad have accepted the invitation to attend, among whom may be named Mr. B. E. Brodhurst, Mr. Thomas Bryant, Mr. A. E. Durham, Mr. Reginald Harrison, Sir William MacCormac, Mr. Howard Marsh, Dr. William M. Ord, Mr. Frederick Treves, and Mr. U. Pritchard, of London; Mr. Robert Jones, of Liverpool; Dr. W. T. Gairdner, of Glasgow; Mr. E. H. Bennett and Professor J. J. Cunningham, of Dublin; Professor John Chiene and Dr. J. Battey Tuke, of Edinburgh; Mr. G. A. Wright, of Manchester; Dr. F. Beely and Professor H. Krause, of Berlin; Professor Cursch-

mann, of Leipzig; Professor Hoffa, of Wuerzburg; M. Emil Javal, Dr. Loewenberg, Dr. Pozzi, and M. Paul Redard, of Paris; Dr. Von Mozegeil, of Bonn; and Dr. Rafael Lavista, of Mexico.

As other societies will meet in this city during the Congress week, it will be prudent for members and visitors to secure hotel accommodations in advance. The Arlington offers accommodations at the rate of four dollars per day, and the Hotel Arno at three and four dollars a day on the American plan, or one dollar a day per room only, on the European plan.

The Committee will take pleasure in answering any inquiry relating to the local arrangements of the Congress.

OFFICERS OF THE CONGRESS.

President, S. Weir Mitchell, M.D.

Vice-Presidents, ex-officio Presidents of Constituent Societies.

Chairman of Executive Committee, William Pepper, M. D., Philadelphia, Pa.

Treasurer, John S. Billings, M.D., Washington, D. C.

Secretary, William H. Carmalt, M.D., New Haven, Conn.

COMMITTEE OF ARRANGEMENTS.

Samuel C. Busey, M.D., Chairman, 1545 I Street N. W., Washington, D. C.

John S. Billings, M.D., Army Medical Museum, Washington, D. C.

W. W. Johnston, M.D., 1603 K St., Washington, D. C.

R. T. Edes, M.D., 1214 18th St., Washington, D. C.

S. O. Richey, M.D., 732 17th St., Washington, D. C.

J. Taber Johnson, M.D., 1728 K St., Washington, D. C.

Sam'l S. Adams, M.D., 1632 K St., Washington, D. C.

I. E. Atkinson, M.D., 605 Cathedral St., Baltimore, Md.

C. F. Bevan, M.D., 807 Cathedral St., Baltimore, Md.

Samuel Johnson, M.D., 204 Monument St., Baltimore, Md.

Samuel Theobald, M.D., 304 Monument St., Baltimore, Md.

H. Newell Martin, M.D., Johns Hopkins Hospital, Baltimore, Md.

D. Forest Willard, M.D., 1818 Chestnut St., Philadelphia.

D. S. Lamb, M.D., 800 10th St., Washington, D. C.

The University Marine Biological Association.

This association was founded for the purpose of establishing and maintaining laboratories and aquaria on the coast of the United States, where accurate researches may be carried on, leading to the improvement of the biological sciences and especially to an increase of our knowledge as regards the food, life-conditions and habits of American food-fishes and mollusks, and for stimulating public interest in these matters. The location of the first laboratory is at Sea Isle City, N. J. The importance of possessing seaside laboratories at which the working naturalists of the country, the teachers in schools and colleges, the patient investigators in pure science, the gov-

ernment experts, and others, could secure a practical acquaintance with the structure and habits of marine animals, has long been appreciated in Europe. It is proposed to issue, at irregular intervals, monographs which shall deal with the structure and life-history of the types of life in this region, written in a style which shall be clear to the uninitiated reader while retaining strict scientific accuracy. These monographs are to be well illustrated, and a special publication fund should be secured at as early a date as possible. To-day our Government and State fish hatcheries are the patterns for the world, and our agricultural experimental stations are proving of untold benefit to those who till the soil or raise domestic animals. But in one direction we are still sadly behind the times. Until very recently America has had no well-established laboratories offering facilities for the study of the lower forms of marine life, and her naturalists have been obliged to accept the courtesy of foreigners for their opportunities of gaining an acquaintance with those smaller forms which are either valuable in themselves, or serve as sources of food supply for valuable fishes, etc.

An annual report, summing up the result of the season's work and calling attention to the achievements and needs of the Laboratory, will be published, to be distributed among the legislators of New Jersey and other States, to the members of the University Marine Biological Association, and to the general public, that they may become aware of the importance of giving encouragement to laboratories of this character.

The number of naturalists who can be employed in special investigation, and definitely retained for the purpose of carrying on their researches throughout the year, must depend on the funds subscribed by private individuals and public bodies for the purpose. The first charges on the revenue of the Association are the workings of the sea-water circulation in the tanks, stocking the tanks with marine plants and animals and feeding the latter, the payment of servants and fishermen, the hire and maintenance of fishing boats, and the salary of the Director, the Scientific Staff and Laboratory Corps. These are the only salaried officers of the Association.

The Marine Biological Association urgently needs additional contributions for the establishment of a sinking fund and for the purchase and maintenance of a sea-going vessel, by means of which investigations can be extended to all such points of the coast as may be of interest in regard to their food products (fish, oysters, clams, lobsters, etc.), to keep the Laboratory open throughout the entire year: to increase the permanent staff engaged at Sea Isle City, and to secure and maintain a library of the necessary books of reference.

The purpose of the University Marine Biologi-

cal Association, like the Association founded a few years since in England ("The Marine Biological Association of the United Kingdom"), is to aid at the same time both science and industry. It is national in character and constitution, and its affairs are watched over by the Trustees of the University of Pennsylvania without any charge upon its funds, so that the whole of the subscriptions and donations received are devoted absolutely to the support of the Laboratory and the prosecution of its work.

WHAT SHALL BE DONE FOR A PATIENT WITH A FOREIGN BODY IN ONE OF THE BRONCHI.—

Dr. J. D. Rushmore says the age, condition of the patient and state of the respiratory organs, as well as the size, shape, weight, etc., of the foreign body should be taken into account before advice is given. A foreign body in a bronchus is always a menace to life, as it causes ulceration, hæmorrhage, abscess, pneumonia, bronchopneumonia, pulmonary thrombosis, etc., in proportion to the firmness with which it is held, and should it become loose, asphyxia, œdema or both may occur. Other methods than those used up to the present time are justifiable when we consider that the failure to extract foreign bodies from the bronchus is 78.38 per cent. The cause of anxiety in the operation through the anterior wall of the chest is the possibility of wounding the pulmonary vein. The posterior or Nesiloff operation is less difficult and much less dangerous. It consists in opening the thoracic cavity into the posterior mediastinum from behind, by the resection of four ribs, without touching the pleura. The posture of the patient is on the abdomen, the arm abducted and raised. A vertical incision is made parallel to the vertebral column, and at a hand's breadth to the left, through the whole thickness of the parts; two horizontal incisions are carried toward the vertebræ, running from the extremities of the vertical incision; a flap is dissected back and a subperiosteal resection of the third, fourth, fifth and sixth ribs is done separately. The pleura is easily pushed forward and the bronchus found. A preliminary opening below or into the pharynx should be made before resorting to inversion, striking the chest, etc., to dislodge a foreign body, thus preventing the danger from asphyxia should it remain in the larynx. Experience in the management of such cases support the following conclusions: 1. A foreign body in a bronchus is always a source of danger to the patient and its spontaneous expulsion is very exceptional and may be long delayed, thus causing inflammation and its results, which is more frequent than asphyxia. 2. The dangers of operative interference should not prevent an attempt at the earliest possible removal, which should be preceded

by a preliminary opening into the larynx or trachea. 3. After a reasonable search through the trachea and bronchus, opening the thoracic cavity in front of the mediastinum or pleural cavity posteriorly is justifiable; all operative measures being done at a single operation if possible.—*N. Y. Medical Journal*, July 25, 1891.

A New Method of Direct Electrization of the Stomach.

Electricity has for a long time held so important a place in the treatment of visceral diseases that it is surprising that so little has been accomplished in perfecting a method for its application to the stomach, one of the most readily reached of all internal organs. In 1877, Kussmaul began to practice direct electrization of the stomach by means of an olive-shaped electrode introduced upon the extremity of an insulating stomach-tube, but the apparatus was clumsy, and, because of its direct contact with the visceral wall, forbade the use of a galvanic current. Bardet's improved electrode (1884) was a distinct advance, but was inconvenient and even impracticable for all but patients well accustomed to lavage of the stomach.

FEINHORN (*Medical Record*, May 9, 1891), has constructed an electrode on the principle of his "Stomach bucket," and proposes for it the name "Deglutible Stomach Electrode." It consists of a hard-rubber capsule (about one and one quarter inches in length) perforated with numerous openings, this cage serving to protect the metal knob within from direct contact. The connecting wire runs through a fine flexible rubber tube. The capsule is readily swallowed and tolerated by the patient, and contact is secured, as in Bardet's electrode, by water in the stomach. The faradic current has been generally employed, and in all cases the degree of acidity of the stomach has been markedly increased. The author makes a preliminary report, which goes to show that most decided results have been obtained in cases of dilatation and in grave cases of chronic gastric catarrh. Two cases of pure gastralgia showed an amelioration after use of the constant current. The majority of cases of hyperacidity were improved, but required the administration of alkalies in the usual way.

NEW METHOD OF DRESSING THE CHEST IN PNEUMONIA AND PLEURISY.—The following method is recommended by Dr. William Hunt: A very thin layer of cotton is applied over the affected side, from spinal column to sternum, and secured with collodion smeared thoroughly over it by means of a broad brush, like a mucilage brush. Then add thicker layers, securing them in turn with collodion, until a good padding is

obtained, paying particular attention to the edges. In double cases the dressing may encircle the chest. The advantages are: 1. The one dressing, if well applied, will last throughout the case; and hence, 2, the fatigue and discomfort of frequent poulticing are avoided. 3. The side, in unilateral cases, is held as in a splint, while the free side does the breathing. A first-class non-conductor is covering the chest. The contracting collodion may have some influence in controlling the blood supply. 4. There is no particular interference with physical examination, to one who has a good ear. Maybe it would be a good thing if there was; for, having once made the diagnosis, what is the use of exhausting the patient every day by trying to find out whether 18 of an inch, more or less, is involved? The general symptoms will tell that.—*Annals of Gynecology and Pediatrics*.

A WRITER in the *British Journal of Dermatology* relates that, after using his thumb nail to remove softened warts, three warts developed on his thumb, confirming him in a view which he had entertained on other evidence, that the popular belief in the contagiousness of warts is well founded.

BOOK REVIEWS.

TWELVE LECTURES ON THE STRUCTURE OF THE CENTRAL NERVOUS SYSTEM, FOR PHYSICIANS AND STUDENTS. BY DR. LUDWIG EDINGER, Frankfort-on-the-Main. Second Revised Edition, with 133 Illustrations. Translated by Willis Hall Vittum, M.D., St. Paul, Minn. Edited by C. Eugene Riggs, A.M., M.D., Professor of Mental and Nervous Diseases, University of Minnesota; Member of the American Neurological Association. Philadelphia and London: F. A. Davis. 1890.

The present volume of 225 octavo pages contains a series of twelve lectures delivered by Dr. Edinger, of Frankfort-on-the-Main, upon the minute structure of the brain. In the translation of a second edition, under date of 1890, the author pays a special tribute to the labors of American physicians, and very courteously recognizes the valuable services which Dr. Vittum as Translator, and Dr. Riggs as Editor, have rendered in thus enabling him to bring this work into relation, as he says, with English-speaking physicians.

In these twelve lectures the method of studying nervous structures, the embryology and comparative anatomy of the brain in general, as also its regional anatomy and its varied relations, are carefully described and amply illustrated.

Those who desire to attain to the latest discoveries in the minute anatomy of the brain, medulla and spinal cord, will find in this work, in compact form, a reliable statement of the most recent investigations upon the subject.

Dr. Edinger has published annually since 1886, in Schmidt's *Jahrbücher*, a statement of the yearly advances made in the study of cerebral anatomy. Those who wish to keep fully abreast of his teachings will do well to consult these annual reviews.

TEXT-BOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY. By JOHN J. REESE, M.D., Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania; Late President of the Medical Jurisprudence Society of Philadelphia, Honorary Member of the New York Academy of Anthropology, Corresponding Member of the New York Medico-Legal Society, etc. Third Edition, Revised and Enlarged. Philadelphia: P. Blakiston, Son & Co., 1012 Walnut St. 1891.

It may safely be said, that in no department of medical teaching in the United States has there been such shortcoming, as in that of medical jurisprudence and toxicology. The result has been that physicians have not infrequently brought discredit to themselves and to their profession by signal and conspicuous failures, when called to occupy the witness' stand. Not that elaborate works were wanting upon these subjects—for the abilities of such writers as Beck, Taylor, Caspar Wharton Stillé and others are everywhere recognized—but their elaborate works demanded more time for careful study than students were able to command, while, in large measure, our medical colleges have failed to emphasize the necessity of a most thorough acquaintance with these subjects. The result has been that, in a very great majority of instances, after graduation physicians have failed to perfect themselves in these fields of study, and oftentimes their deficiencies have been disclosed to the public in open court, in a manner much to their discredit.

In the present volume the essentials of the science of legal medicine are tersely and clearly set forth in a single volume of 650 pages. The rules to be observed by experts, the phenomena and signs of death, post-mortem appearances, the identification of the dead, the nature and extent of wounds, and causes of death, are among prominent topics considered in the first 200 pages.

The subject of toxicology holds a prominent place in the work. The various poisons and their antidotes are carefully considered. The toxic influence of ptomaines is the subject of a newly written and interesting chapter. Feigned diseases, criminal abortion, infanticide, legitimacy, impotence, rape, insanity, malpractice, liabilities of druggists, and kindred topics, com-

plete the volume. It will be found admirably adapted to class work, as that form of teaching is becoming more and more prominent in our medical schools.

The fact that a third edition has been so soon in demand, is evidence of the need of such a work on the part both of students and practitioners, and its very extended sale is also evidence of the satisfactory manner in which the work is meeting that need.

THE POCKET ANATOMIST. Founded upon Gray. By C. HENRI LEONARD, A.M., M.D., Professor of the Medical and Surgical Diseases of Women and Clinical Gynecology, in the Detroit College of Medicine. Fourteenth revised edition, containing Dissection Hints and Visceral Anatomy. Detroit: The *Illustrated Medical Journal* Co., Publishers. 1891. Cloth, 297 pages, 193 Illustrations. Price, postpaid, \$1.

An excellent little book, which the title fully describes. It is well illustrated by plates reduced from Gray.

A DICTIONARY OF PRACTICAL MEDICINE, by Various Authors. Edited by James Kingston Fowler, M.A., M.D., Fellow of the Royal College of Physicians; Senior Assistant Physician to the Middlesex Hospital, and Lecturer on Pathological Anatomy in the Medical School; Senior Assistant Physician to the Hospital for Consumption and Diseases of the Chest, Brompton. Philadelphia: P. Blakiston, Son & Co., 1012 Walnut Street. 1890.

This is a concise and valuable octavo volume of over nine hundred pages, representing the views of some forty different English writers with reference to the nature and treatment of the various diseases which are by them severally considered, the unsigned articles being in the main written by the Editor and by Mr. John Abercrombie. The wide range of subjects referred to renders it really a condensed cyclopædia of the practice of medicine. A careful examination of a large number of the diseases described and the methods of treatment advised, renders it evident that the work will prove one of special value to practicing physicians, especially for purposes of ready reference.

The details of treatment are so fully given, that one may at the moment come upon the views of the writer, and in the main the suggestions are eminently practical and judicious. The subjects are arranged in alphabetical order, rendering it, as its title indicates, a very complete dictionary of practical medicine. It includes, beside the diseases usually considered in works of practical medicine, those also peculiar to women. The younger members of the profession especially will find it to their advantage to obtain this work, and carefully consult its teachings.

NECROLOGY.

Abraham Coles, M.D., LL.D.

The sudden death of Dr. Abraham Coles, of Newark, N. J., in June last, at the Hotel Die-monte, near Monterey, Cal., was a loss not only to the medical profession, but to the community in which he had lived for so many years, and to the world of literature which he had graced by numerous classical and poetical contributions. Dr. Coles and his son, Dr. J. A. Coles, were members of the Pennsylvania Railroad excursion party that left Newark on April 14, for a visit of several weeks to the Pacific Coast, during the latter part of which he suffered from a severe attack of grippe. His death was due to some complication arising from it. Dr. Coles was born at Scotch Plains, N. J., December 26, 1813. His father was a well-known printer and publisher of his day, and a man of rare literary taste and judgment. Dr. Abraham Coles, in the earlier years of his life, devoted himself to literary pursuits. At the age of 17 he was teacher of Latin and mathematics in a private school at Plainfield. Here he turned his attention more particularly to the law, but gave up the study to enter Jefferson Medical College, graduating in 1835. In 1836 he settled in Newark, where he soon established an extensive and lucrative practice, and made for himself a wide reputation as a skilful physician and surgeon. In 1842, he married Caroline E., daughter of Jonathan C. Ackerman, of New Brunswick. Five years later Mrs. Coles died, leaving one son, now Dr. John A. Coles, and one daughter. Dr. Coles visited Europe, and was in Paris at the time of the revolution of 1848, and did excellent service as surgeon in the French hospitals. He paid a second visit to Europe in 1854. In 1860 the University at Lewisburg conferred upon him the degree of Ph.D., and in 1871 Princeton College that of LL.D.

Dr. Coles' literary work was voluminous and erudite. His love for the classics and his bent of mind led him to Greek, Latin and Oriental literature as a student and explorer. His metrical versions of the Psalms were original translations as well as versified transcriptions. He translated and printed, in 1847, his own version of the famous Latin hymn, "Dies Iræ," and in 1859 republished this in another volume with twelve other versions by other hands. In 1866, he printed "The Microcosm," a physiological poem, originally delivered before the New Jersey Medical Society, of which he was then President. In 1847 he had published the first part of "The Evangel," which was the Life of our Lord in verse, with texts and notes, and in 1881 he put forth a volume which, under the title of "The Microcosm and Other Poems," included all of

his more important translations and original poems. His "Latin Hymns" appeared in 1868; his "Light of the World" in 1884; his versified edition of the Psalms of David in 1889.

Karl Marx, M.D.

Dr. Karl Marx, a Moravian missionary of note, whose home for five years has been some 11,300 feet above sea level in the mountains of Western Thibet, died May 29, from an attack of influenza and pneumonia. His station was at the little mountain village called Leh, in the province of Ladak, on the highroad to Chinese Thibet, the only remaining hermit nation of Central Asia. Consumption is said to be unknown at Leh, and it has been one of the complaints of Dr. Marx that the people there were generally so strong and well, that they gave him very little to do. In a recent number of the *London Practitioner*, Dr. Marx expressed the opinion that the infectious diseases, when introduced into the Thibet Highlands, where he dwelt, became modified and mitigated. For example, he mentioned that small-pox is said to be converted into a disease resembling varicella, and rabies, though frequent and fatal among the canine species, does not beget hydrophobia in the human subject, as it does in the more southerly valleys of Lahore. He thought that when his lofty region should become less difficult of access, there could be established there a sanitarium for all sorts and conditions of human diseases. All the members of the missionary outpost at Leh were taken ill with the influenza, and they suffered severely, but only one adult was carried off by it.

DR. THOMAS L. SMITH, a retired Medical Director of the Navy, died August 14, at Brooklyn. He was born at Orange, N. J., ninety-one years ago. He entered the public service in 1828, as surgeon's mate, and was retired about twenty years ago.

DR. GEORGE H. LYMAN, formerly physician to the Boston City Hospital, died in London, England, August 19, at the age of seventy-two years. He had been member of council in the American Gynecological Society, and author of an exhaustive essay on the history and statistics of ovariectomy. During the late war, he held important positions, becoming medical inspector in the Army, with the rank of lieutenant-colonel.

DR. JOHN JEFFERSON DEMENT, an ex-president of the Alabama Medical Association, died August 10, at Lithia Springs, Georgia. He was prominent in all the educational and medical institutions in Huntsville, where his home was, and in its vicinity. He was also trustee of Van-

derbilt University, Nashville, Tenn. He served as surgeon with Lee's army during the whole of the late war, except during a period of imprisonment at Camp Chase, which lasted about four months. His death took place, when he was in his sixty-second year, from renal disease.

MISCELLANY.

DR. H. F. EWERS has removed from Union City, Mich., to Burlington, Ia.

AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.—The first annual meeting of the American Electro-therapeutic Association, will be held at Philadelphia, Pa., September 24th, 25th, and 26th, 1891, in the hall of the College of Physicians, cor. 13th and Locust sts.

First Day, Thursday, September 24, 3 p.m.

1. President's Address, by Dr. G. Betton Massey, Philadelphia.
2. Electro-Therapeutics in America; An Historical Survey, by Dr. A. D. Rockwell, New York.
3. The Action and Application of the Faradic Current in Gynecology, by Dr. Augustin H. Goelet, New York.
4. Alternative Currents, Dr. Horatio R. Bigelow, Philadelphia.
5. The Treatment of Corneal Opacities by Galvanism, by Dr. C. A. W. Alleman, Brooklyn, N. Y.

Second Day, Friday, September 25, 10 A.M.

6. Report of Seventy-five Cases of Uterine Myomata Treated by Electricity, by Dr. J. H. Kellogg, Battle Creek, Mich.
7. Two Cases of Fibroids where Electricity Ceased to control Hæmorrhage after a time, although eminently satisfactory at first, by Dr. H. E. Hayd, Buffalo, N. Y.
8. The Treatment of Fibroids by Electricity, by Dr. W. H. Hutchinson, Providence, R. I.
9. Electro-Puncture in Uterine Fibroids, by Dr. G. Betton Massey, Philadelphia.
10. Electricity in Chronic Parametritis, by Dr. Von Raitz, New York.
11. Report of a Case, by Dr. A. H. Buckmaster, Brooklyn.
12. Some New Applications of Electro-Therapeutics, by Dr. Frederick Peterson, New York.
13. The Analgesic Effects of Galvanism, by Dr. Landon Carter Gray, New York.
14. Electricity in Diseases of the Stomach, with Exhibition of Patient, by Dr. Lawrence Wolff, Philadelphia.
15. Electricity in Carcinoma, by Dr. Robert Newman, New York.
16. Title not Received, Dr. W. J. Morton, New York.
17. Title not Received, Dr. Henry McClure, Cromer, England.
18. Some Points in the Technique of Electrolytic Epilation, by Dr. Plym S. Hayes, Chicago, Ill.
- 8.30 P. M., Business meeting.

Third Day, Saturday, September 26, 10 A. M.

19. A Rare Case of Twin Extra—and Intra—Uterine Pregnancy Treated by Electricity, by Dr. G. H. Whitcomb, Greenwich, N. Y.
20. Electricity in the Treatment of Rheumatism, by Dr. W. F. Robinson, Albany, N. Y.
21. The Treatment of Subacute Articular Rheumatism by Electricity, by Dr. M. A. Cleaves, New York.
22. Electricity in Anchylosis, by Dr. Von Raitz, New York.

23. Has Electricity any Action as a Germicide, or in Producing Poisonous Results in Food, by Dr. W. R. D. Blackwood, Philadelphia.

24. Exhibition of a Rectal Electrode, with Remarks on its Application, by Dr. Guy Hinsdale, Philadelphia.

25. Abdominal Electro-Puncture in an Ovarian Tumor, by Dr. G. Betton Massey, Philadelphia.

26. Eight Months' Work in the Dispensary for the Treatment of the Diseases of Women, by Electricity, by Dr. H. R. Bigelow, Philadelphia.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS. SECOND TRIENNIAL SESSION.—The Trunk Lines, the New York and Boston Lines, the Southern Passenger Association, and the Central Traffic Association, will transport persons wishing to attend the Congress from points on their lines to Washington and return at the price of one and one-third the regular fare on the following conditions:

The going ticket must be purchased within three days before the opening date of the meeting.

Each person availing himself of the concession must pay full first-class fare going to the meeting, and must obtain a certificate from the agent of whom the ticket is purchased.

Those holding such certificates, when countersigned by the proper officer at the Congress, can obtain return tickets at one-third the highest limited fare.

Certificates are not transferable, and the return tickets secured upon certificates are not transferable. If any of them are sold or transferred they must be redeemed at the highest first-class rate by the person making such sale or transfer.

No certificates will be countersigned at the Congress except those presented by physicians attending the Congress, or their wives and members of their families; nor will any certificate be countersigned after September 26.

No refund of fare will be made on account of any person failing to obtain a certificate.

Those who wish to avail themselves of this method of obtaining reduction in fares, should present themselves at the office for certificates and tickets at least 30 minutes before departure of trains.

It is absolutely necessary for each passenger before starting to obtain a certificate from the ticket agent of whom the going ticket is purchased, otherwise he can obtain no reduction in the return fare.

There will be no stop-over privileges on the return tickets, which must always be by the same route as the going ticket.

Members may obtain tickets on these conditions for their wives and members of their families, as well as themselves.

Tickets for the return journey will be furnished only provided the *properly countersigned certificates* are presented to agent at return starting point within three (3) days after the adjournment of the Congress, Sunday not to be counted as a day.

By order of the Committee of Arrangements.

SAMUEL S. ADAMS, M.D.,

in charge of R. R. matters.

1632 K Street, Washington, D. C., August 18, 1891.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from August 22, 1891, to August 28, 1891.

Capt. James E. Pilcher, Asst. Surgeon U. S. A., is relieved from duty at Ft. Clark, Tex., on expiration of leave of absence, and is assigned to duty at Ft. Ringgold, Tex.

Capt. M. C. Wyeth, Asst. Surgeon U. S. A., sick leave of absence extended three months on surgeon's certificate of disability. Major Valery Havard, Surgeon U. S. A., granted three months' leave of absence, to take effect on or about September 5, 1891.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending August 29, 1891.

P. A. Surgeon F. A. Hesler, detached from U. S. S. "Pensacola," and to the U. S. S. "Charleston."

The Journal of the American Medical Association

CHICAGO, SEPTEMBER 12, 1891.

No. 11.

ORIGINAL ARTICLES.

ORIGINAL INVESTIGATIONS ON THE HEATING AND VENTILATION OF SCHOOL BUILDINGS.

Read in the Section of State Medicine, at the Forty-second Annual Meeting of the American Medical Association, at Washington, D. C., May, 1891.

BY R. HARVEY REED, M.D. (UNIV. OF PENN.),
OF MANSFIELD, O.

Member Committee of School Hygiene of the Section of State Medicine, American Medical Association; Member American Public Health Association; British Medical Association; National Association of Railroad Surgeons; Ohio State Medical Society; President North Central Ohio Medical Society; Health Officer, Mansfield, O.; Surgeon Baltimore and Ohio R. R.; Honorary Member D. Hayes Agnew Surgical Society, Phila.; Texas State Medical and State Sanitary Association, etc.

At the meeting of the American Medical Association, held at Newport, R. I., two years ago, a special committee was appointed by the Section of State Medicine on "school hygiene," consisting of Dr. D. F. Lincoln, Geneva, N. Y.; Dr. J. A. Schenck, Topeka, Kan.; Dr. Geo. H. Rohé, Baltimore, Md.; Dr. J. G. Pinkham, Lynn, Mass.; and the author.

After some correspondence, it was decided to divide the work of this committee, and as a result, I was assigned the "original investigations on the heating and ventilation of school buildings."

After no small amount of research among the multiplicity of reports of the numerous air analyses of the different school-rooms in the various cities, I found them all practically valueless, so far as making anything like a systematic comparison of results was concerned, of even an approximately scientific character.

By this I mean to say that they all lacked the details regarding those numerous modifying elements, which of necessity surround each individual room; such as the temperature *outside* of the school building; the temperature *inside* of the same at the level of the floor, mouth and ceiling, both in the front and at the rear of the room, the same observations regarding the humidity, as well as that of the carbon dioxide; the number of scholars present; the size of the room; the method of heating the same, as well as the system of ventilation employed; the amount of fresh air supplied, and the quantity of foul air discharged from a room, in a given time, together

with the barometric pressure—each one of which is an important arc of a complete circle; and of necessity must all be considered together, and due credit given each one, in order to obtain anything like definite or reliable information regarding any special method or system of heating and ventilating a given room or a certain building.

With a view of obtaining the most reliable results possible, I devised a blank chart, which I thought would, as near as possible, contain all these more important factors.

I then determined to pursue the same line of investigation, of different school-rooms in the same building; and different buildings in the same city; and different cities in the same State; among which I designed to embrace as large a variety of the various methods of heating and ventilation, as we practically could, and to repeat our examinations sufficiently often on the same systems, when at all practical, to enable us to arrive at some definite conclusions, regarding any special method of heating and ventilation, if such were at all possible.

As a result, I prepared a chart which embraces the following details:

- 1st.—Date and time of day inspection was made.
- 2nd.—Name of school building.
- 3rd.—Name of school-room.
- 4th.—Number of pupils present.
- 5th.—Number of cubic feet of air contained in the room.
- 6th.—Temperature outside of the building.
- 7th.—Humidity outside of the building.
- 8th.—Barometric pressure in inches.
- 9th.—State or condition of the weather.
- 10th.—Kind of heating apparatus in use.
- 11th.—System of ventilation employed.
- 12th.—Number of cubic feet of fresh air supplied per hour.
- 13th.—Number of cubic feet of foul air discharged per hour.
- 14th.—Temperature at the front of the room. *a*, at the floor; *b*, at the mouth; *c*, at the ceiling.
- 15th.—Temperature at the rear of the room. *a*, at the floor; *b*, at the mouth; *c*, at the ceiling.
- 16th.—Humidity at the front of the room. *a*, at the floor; *b*, at the mouth; *c*, at the ceiling.
- 17th.—Humidity at the rear of the room. *a*, at the floor; *b*, at the mouth; *c*, at the ceiling.

18th.—The amount of carbon dioxide found in the air of the city per 10,000 parts.

19th.—The amount of carbon dioxide per 10,000 parts found in the air in the front of the room. *a*, at the floor; *b*, at the mouth; *c*, at the ceiling.

20th.—The amount of carbon dioxide per 10,000 parts found in the air at the rear of the room. *a*, at the floor; *b*, at the mouth; *c*, at the ceiling.

BACTERIOLOGICAL INVESTIGATION.

21st.—Germs found in the air of school-rooms when occupied. *a*, near the floor at the point of entrance of the fresh air; *b*, near the floor at point of exit of foul air.

22nd.—Miscellaneous observations.

Having completed the general plan of investigations, I then determined to investigate, as far as practicable, the following methods of heating and ventilating school rooms.

1st.—School rooms warmed by common stoves, with and without any provisions for ventilation, other than windows, doors and transoms.

2nd.—School rooms warmed by small furnaces placed in each room, which heated fresh air received from the outside, and delivered it to the room, with and without provisions for the escape of the foul air, other than that furnished by the doors, windows and transoms.

3rd.—School rooms warmed by furnaces or heaters, and ventilated at the top.

4th.—School rooms warmed by furnaces or heaters, and ventilated at the floor.

5th.—School rooms warmed by furnaces or heaters, and ventilated at the floor and ceiling both.

6th.—School rooms warmed by direct steam and ventilated by doors, transoms and windows.

7th.—School rooms warmed by indirect steam and only ventilated by foul air ducts, windows and transoms.

8th.—School rooms warmed by both direct and indirect steam and ventilated by foul air shafts, windows and transoms.

9th.—A school room warmed by direct steam, and ventilated by an open fire place and a top ventilator.

10th.—School rooms warmed by a furnace which delivers the hot air to the room at the floor, and which room is also supplied with cold fresh air at the floor, and is provided with means for removal of foul air at the top of the room.

11th.—School rooms warmed by an air warmer, which supplies the warm air at the floor, and removes the foul air at the floor without the aid of open doors, windows or transoms.

After having completed the outline of these proposed investigations, I next found it quite a difficult task to secure the services of a competent chemist, who was willing and able to undertake the work I had laid out. But after corresponding with the chemists of several cities, I obtained the services of Prof. Lewis Schmidt, B.

Sc. (Mass. Institute of Technology), of Cincinnati, Ohio, to undertake the chemical investigations, together with the humidity, temperature, etc., etc.; which he conducted throughout the entire investigation for me, in a perfectly satisfactory manner.

The original report contemplated the examinations for carbon monoxide (CO) but as this product is seldom found in the air, except when it has been passed for a considerable period, of at least two hours, over red hot iron plates, we decided to omit this part of the report, and also the examination for organic matter, owing to the impractical character of the former, and the unreliable methods of determining with any degree of scientific accuracy the latter.

Arrangements were supposed to have been made with a couple of bacteriologists to complete the bacteriological part of the work in a systematic manner. But when their work was received, it was found to have been conducted in such a *helter-skelter* manner, as to render it utterly valueless for this report, and in consequence I was compelled to omit it entirely. In fact I don't think it has detracted anything from the practical value of the report at best; my experience in this direction, has led me to conclude that there is little to be derived from this particular field, of a practical character, that will effect either the heating or ventilation of school rooms, either pro or con. Yet if properly conducted in a *systematic* manner, it might be made to serve the purpose of proving whether the germs are increased or diminished in quantity, from the time the air enters the room until it leaves it, and approximately to what extent, and under what circumstances. Outside of this I cannot conceive of any particular value to be derived from it; and certainly not when made without any apparent reference to a definite object, as was done in this case.

I next selected Cleveland, Mansfield, Columbus and Cincinnati, Ohio, for the cities in which I would conduct the proposed investigations; and to which I gave my personal attention, in Mansfield and Cleveland, and in part my personal attention in Columbus and Cincinnati, but least so in the latter, having only visited a few of the school rooms in that city, owing to unavoidable circumstances, which prevented my presence during the investigations there.

My instructions were to make investigations of each room, as near as possible under the conditions it was usually kept in, and to be very careful to leave nothing undone that would enable us to obtain the highest degree of accuracy possible, regardless of the system of heating and ventilation we were investigating, as we were seeking actual facts, for scientific purposes, let them reveal what they would.

In carrying out these investigations, we have

made altogether 224 determinations of the carbon dioxide, not including the examinations of the outside air; 233 determinations of the humidity, not including those made outside of the buildings; and 232 examinations of the temperature exclusive of those made outside of the buildings; saying nothing of the numerous other auxiliary observations of surrounding conditions.

These examinations were made in 39 different school rooms, of 23 different school buildings, in 4 different cities, and include 10 different systems of heating and ventilation.

By referring to the itemized charts, you will observe that we have examined the air in 10 rooms in Mansfield, 7 rooms in Cleveland, 4 rooms in Columbus, and 18 rooms in Cincinnati: which embraced 11 rooms heated by the so-called Grossius system; 11 rooms warmed by the Smead system; 5 by the Johnson system; 3 by indirect steam; 3 by common stoves; 2 by direct steam; 1 each by the Patric and Miller furnaces; direct steam with an open grate, and direct and indirect steam. You will also observe that we have made 6 examinations each, of the temperature, humidity and carbonic dioxide in each room, viz.: two each at the floor, one each in the front and rear of the room; two at the mouth, one each in the front and rear of the room; and two at the ceiling, one each at the front and rear of the room; besides all the supplementary investigations we have associated with these three primary determinations.

In making these investigations we used tested Fahr. thermometers for obtaining the temperature; whilst a carefully constructed hygrometer was used for determining the amount of moisture contained in the air, the scale of which was so constructed as to represent complete saturation at 100 and complete dryness at 0. For determining the velocity of the currents of air, we used a delicately constructed anemometer, which would register the velocity of any current of air, that was moving over 30 feet a minute. By means of glass rods, rubber hose and a small bellows, we could obtain air from any desired part of the room, a given quantity of which was pumped into clean dry bottles, of a known capacity, which were carefully corked and labeled, and taken to the laboratory for the determinations of the CO₂ which was obtained by neutralizing the carbon dioxide with a barium solution of a known quantity and strength, and calculating the amount of CO₂ per 10,000 parts of air from that, in the usual manner, which is familiar to all practical chemists.

By referring to these itemized charts, one of which has been prepared for each city, in which examinations of the air was made, you will observe that with the exception of the Smead system, either doors, windows and transoms, or all, were relied on for ventilating and regulating the temperature of the room.

From these *itemized charts* we have compiled a number of tables which embrace:

1. The highest and lowest temperature, and the highest and lowest humidity, outside of the building examined, and also the average temperature and humidity of the air of the city, which we have shown: *a*, as found in each city; *b*, as found associated with each system of heating and ventilation; *c*, the general average of each.

TABLE I.

Showing the highest and lowest temperature and the highest and lowest humidity outside of the buildings, together with the average of the same, by cities.

LOCATION.		Temperature, outside of the Building, Fahr.	Humidity outside of the Building, based on 100 for complete saturation.	Total number of examinations made.
Mansfield, Ohio.	Highest	35.0	89.8	10
	Lowest	27.5	46.3	
	Average	32.0	71.1	
Cleveland, Ohio.	Highest	55.2	89.5	7
	Lowest	33.0	35.4	
	Average	45.3	49.0	
Columbus, Ohio	Highest	53.0	59.4	4
	Lowest	44.5	42.3	
	Average	49.5	50.8	
Cincinnati, Ohio	Highest	69.0	100.0	18
	Lowest	33.5	48.0	
	Average	52.0	75.3	
Grand average for the four cities above named out of 39 examinations	Highest	52.0	75.3	Total 39
	Lowest	32.0	49.0	
	Average	44.9	61.5	

2. The highest and lowest temperature, and the highest and lowest humidity inside of the school rooms examined, together with the average of the same: *a*, as found in each city; *b*, as found associated with each system of heating and ventilation; *c*, the general average of each.

3. The highest and lowest amount of carbon dioxide found per 10,000 parts of air, inside of the school rooms, and the average of the same: *a*, as found in each city; *b*, as found associated with each system of heating and ventilation; *c*, the general average of each.

4. The average amount of carbon dioxide found per 10,000 parts in each city.

Before commencing the study of these tables it might be well to remark that 70° Fahr. is a fair average standard to adopt for the temperature of a school room, and from 40 to 50 for the ideal range of humidity, and whilst the CO₂ varies in different cities, and on different days in the same city, and at different times in the same day, yet we have found that the general average in the four cities under consideration, was 4.853 parts in 10,000 parts of air, which we will be obliged to use in this case for the standard of our comparisons.

We will readily observe that tables Nos. 1 and 2 are only designed to prepare us for those which are to follow, by giving us the *outside* relations of the same conditions we are about to consider *inside* of the school rooms.

TABLE II.

Showing the highest and lowest temperature and the highest and lowest humidity outside of the buildings, together with the average of the same by systems.

				39

By studying table No. 3, you will observe that we have given the *extremes* of temperatures and humidities, as well as the average temperatures and humidities found in the four cities, *without* regard to the system of heating and ventilation which produced them; whilst table No. 4 considers the same conditions *with* reference to the systems of heating and ventilation that produced these results; whilst table Nos. 5 and 6 show the determinations of carbon dioxide, in the same manner as described for the temperature in tables No. 3 and 4.

The limited time and space allotted to this paper will not permit me to enter into a detailed discussion of these numerous tables, which represent a multiplicity of conditions, which modify and change the general results, all of which must be duly considered, in order to arrive at legitimate conclusions.

For the present, at least, I will have to content myself with giving you an accumulation of data, which I will be obliged to leave for you to study at your leisure; whilst I proceed to consider some of the more prominent features of this report.

THE HEATING.

By examining this report you will observe, that we have examined quite a variety of methods of heating, which has shown a still greater range of temperature, which is especially noticeable between the floor and top of the room; but when you come to compare the *general average* of the temperatures taken of the different systems, they vary but little at the same point of the different levels, which at the floor, in the front of the rooms show a range of from 59.5° to 68.8° , and at the mouth in front from 67.0° to 73.8° , and at the ceiling in front from 68.5° to 85.0° , whilst there is quite a difference in the range of the average of the ceiling temperatures, there is a much greater difference observed between the floor and ceiling, which ranges from 59.5° to 85.0° , or a difference of 25.5° .

Again, in the average at the rear of the room, the range of temperatures at the floor varies from 60.0° to 74.5° , and at the mouth from 64.0° to 70.2° ; and at the ceiling from 70.7° to 90.0° ; whilst at the rear of the rooms there was found to be a difference between the lowest average at the floor, and the highest average at the ceiling of 30.0° .

It must be remembered in the study of these results, that with the single exception of the Smead system, the temperature in every instance was modified by open doors, windows or transoms, and not unfrequently all of them. In the majority of instances the windows were open several inches between the sash and very frequently at the top, and often at the bottom; and which not unfrequently had a strong ally in the form of an open transom or door. These methods of modifying the temperature, to a certain extent accomplished the desired results, so far as the average temperature was concerned, but at a great expense of fuel and waste of heat; and unavoidable exposure of the pupils to cold and changeable drafts of air.

On the other hand, the Smead system of heating accomplished even better average results, and very much better individual results, at the different levels of the room, than any other system examined, and that, too, without exposing the pupils to cold changeable drafts of air from open doors, windows and transoms; saying nothing of the economy of fuel by the prevention of the unnecessary waste of heat through these objectionable openings in the doors, windows and transoms.

THE HUMIDITY.

The amount of moisture contained in the air

If all five funding sources are included, the total amount available would increase from \$70 million to over \$86 million annually, or about 25% more than what was available under the current system, but owing to the rule and other imperfections of our financing system, we may never see such a large improvement.

The direct and indirect employment generated by four

vents placed in the roof of the building, which there are four in the building central air shaft, which there are four in the building by a furnace and in all

[illegible]

ture *increases*. Yet this condition is very greatly modified by the humidity of the outside atmosphere. For example, take a wet, sultry day, when the humidity of the external air is almost at the point of complete saturation, and at the same time the outside *temperature so high*, that but little artificial heat is required, or can be tolerated, the humidity will be found to be exceedingly high in the school rooms, as a natural result of a combination of circumstances. Again, with the same degree of humidity outside, associated with a *cold raw air* requiring a considerable quantity of artificial heat to make the school room comfortable, the humidity of the school room, whilst somewhat high, will be found much lower than under the former conditions; and at the same time the average temperature will be almost or practically the same.

You will observe by table No. 4, that the average humidity at the floor in front of the school rooms, in the various systems varies from 27.5 to 61.2; whilst at the mouth it ranges from 29.4 to 50.7; and at the ceiling from 19.8 to 49.2. At the rear of the room, it varies at the floor from 25.6 to 50.8, whilst at the mouth it ranges from 33.3 to 51.5; and at the ceiling from 16.5 to 45.0.

By these you will observe that even many of the general averages are entirely too low, although few of them are found to be too high. Yet, notwithstanding all this when we examine the itemized charts and study the individual results in isolated cases, you will find still greater variations of the humidity, in different parts of the same room; and especially so when no regular system of circulating and changing the air has been adopted.

On the other hand, when a regular system of circulating the air has been adopted, it is remarkable how the results are modified regarding the amount of moisture contained in the air at different points in the same room, and even different rooms in the same building.

CARBON DIOXIDE.

Notwithstanding we have advocates at the present time, who question the injurious effects of even large quantities of carbon dioxide in the air of school-rooms, yet I am not prepared to accept their theories, without more than circumstantial evidence to verify their correctness.

We must bear in mind that the presence of large quantities of CO_2 does not necessarily make any physical changes in the air that are readily observed by the senses.

It is true that immense quantities of CO_2 will produce fatal asphyxia, yet it never has been, and no doubt never will be found in such immense quantities as to produce death in school-rooms; but it *is* found in sufficient quantities, in a large majority of school-rooms, as to act as a

slow poison from day to day, during a large portion of the scholars' school life, in proportion to the quantity of CO_2 present, and the corresponding restrictions on the natural supply of fresh air.

The question of where the carbon dioxide prevails in the largest quantities, in school-rooms, has long since been a mooted question. The old authors, as well as public opinion, placed it at the *top* of the room; and as a result of their belief, advised making provisions for its escape at or near the ceiling. On the other hand, the more recent writers affirmed that it prevailed in the greatest quantities at or near the *floor*, of a given room; and cited you to the fact that it was heavier than air, and of necessity must accumulate at the bottom; and produced as evidence to prove their theory, the old cave story—in which a man can walk with impunity, while his dog would be asphyxiated with carbon dioxide, which they backed with the experiment of the model house, in which a large, medium, and short lighted candle was placed, and the air excluded—when the short candle would go out first, the medium next, and the long candle last.

But you must remember that in neither of these cases, is there any circulation of air, and consequently, barring the law of diffusion of gases, there is nothing to intermix the CO_2 with the sundry strata of air, and modify the natural laws of gravitation. On the other hand, we have quite a different condition of affairs in the school-room, which modify the primary laws of gravity, and which give us entirely different results than the imaginary attributes from which we have heretofore woven our theoretic web of supposed conditions regarding the CO_2 , which, however, in fact did not exist, as you will observe by a careful study of the charts and tables which accompany this report.

By turning to table No. 6, you will observe that the highest average of CO_2 found associated with any particular system of heating and ventilation, in the *front* of the room at the level of the floor, was 19.127 parts per 10,000, and the lowest average was 8.754; whilst at the *mouth* the highest average was found to be 17.499, and the lowest at the same level was 9.557; and at the *ceiling* the highest average was found to be 16.493, and the lowest 9.914; which only shows a difference of 1.160 parts in 10,000, between the lowest average at the floor and the lowest average at the ceiling, in favor of the ceiling; and only 2.634 parts between the highest average at the floor, and the highest average at the ceiling, in favor of the floor.

Again, in the *rear* of the room, the highest average of CO_2 at the floor was 16.671, and the lowest 10.240; whilst at the mouth it was 16.971 against 10.285, and at the ceiling 18.223, as compared with 9.751; with only a fraction of .489 difference between the lowest average at the

mouth and the lowest average at the ceiling, in favor of the latter; whilst the difference between the highest average at the ceiling, and the highest average at the floor, was only 1.552 in favor of the ceiling. But go with me, if you please, to table No. 5, and there turn to the grand average of the four cities, taken from 224 determinations, and you will find that there is only a fraction of a difference between the amount of CO_2 at any level of the room, either at the rear or front; which grand average shows in the front of the rooms 13.137 at the floor, and 13.785 at the mouth, and 13.064 at the ceiling. Whilst in the rear of the rooms, it shows 14.350 at the floor, 13.651 at the mouth, and 13.912 at the ceiling; or in other words, only the fraction of .075 difference between the floor and the ceiling in the front of the rooms, in favor of the floor; and but .438 difference between the floor and the ceiling at the rear of the rooms, in favor of the former.

It seems to me that this investigation ought to settle, without a question, the problem regarding the location of the CO_2 in the school-rooms of to day, and especially those which are heated artificially, and to prove beyond a shadow of a doubt, that CO_2 is an omnipresent factor, in practically the same relative proportions at all levels of a school-room, whether ventilated at the top, sides or the bottom, or all.

GENERAL REMARKS.

The next important question that confronts us, after having obtained all this "array of facts and figures," is—how shall we proceed to heat and ventilate our school-rooms in the most sanitary, economical, practical and scientific manner? In answer to these questions I will say:

1st.—That to heat and ventilate our school-rooms in the most *scientific* manner will require a system of heating and ventilation which will avoid the necessity of having either open doors, windows or transoms, and which will at the same time supply each scholar with not less than 1,000 cubic feet of fresh warm air every hour, and which will remove a corresponding quantity of foul air at the same time, without subjecting any scholar in the room to an uncomfortable draught of either cold, or over-heated air. Sufficient fresh warm air should be supplied to each scholar, at an average temperature of about 70° , and an average humidity ranging from 40 to 50; whilst the foul air should be removed sufficiently rapid as to prevent an accumulation of CO_2 to exceed 10 parts in 10,000 parts of air at any time, or in any part of the room, or a variation of the temperature between the floor and the ceiling to exceed 10° Fahr., or at any level of the same between the front and the rear, or either, to exceed 5° Fahr.

2nd.—To accomplish these results in the most *economical* manner will require an air warmer, with sufficient capacity to heat the required

amount of air to the desired temperature without superheating it (for under no circumstances should it be allowed to pass over red-hot iron plates); and which fresh warm air should be discharged in a gentle current at the floor, and exhausted at the same level at the sides of the room, without the assistance of a top ventilator or the aid of an open door, window or transom. But if top ventilators *are* used at all, they should only be used to cool the room, in the event it became *over* heated from any cause; outside of this they are of no value whatever, except to wantonly waste our heat and fuel, without giving us any advantages in return for their loss.

3rd.—I am fully aware of the fact, that it is usually a very difficult task to realize, in a practical manner, the theories that fill us with enthusiasm when demonstrated on paper; and further, that there is perhaps *no* system of heating and ventilation in use at the present time, that is capable of carrying out in every particular, under all possible circumstances, the ideal heating and ventilating of the average school-room, yet after years of investigation, and examining scores of different kinds of heating and ventilating apparatus, without "either fear or favor" to any one, I am thoroughly convinced that there is no system of heating and ventilating at the present time, that will come so *near* fulfilling the requirements of the ideal methods of accomplishing these results, in the most sanitary, economic, practical and scientific manner, as the so-called Smead system. In making the above assertion, I do so in all candor, and without personal favor, or intentional disparagement to any one, but simply as the legitimate conclusion I have derived from actual facts, obtained from repeated personal and scientific investigations.

CONCLUSION.

I trust you will pardon the prosy character of this report, which is largely composed of "facts and figures," which to obtain, has been a tedious, irksome, and an expensive task. Yet if only it serves the purpose of securing a better heated, and more liberal supply of God's pure air to the rising generations, who spend (from a hygienic standpoint at least) the very best and most important part of their lives in our public and private schools, I will feel that all my labors have been fully repaid.

Mansfield, O., April 27, 1891.

KATZENJAMMER.—Resorcin is said to act admirably in cases of nausea and depression following a carouse. It is given in the dose of from five to ten grains in plenty of water, flavored with syrup of orange peel, and may be repeated once or twice at intervals of half an hour. A single dose of ten grains is, however, said to be usually sufficient.—*N. Y. Med. Record.*

THE VALUE OF WEAK CYLINDERS FOR THE RELIEF OF EYE MUSCLE STRAIN.

Read in the Section on Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C. May, 1891.

BY JULIAN J. CHISOLM, M.D.,

PROFESSOR OF EYE AND EAR SURGERY IN THE UNIVERSITY OF MARYLAND, SURGEON-IN-CHIEF OF THE PRESBYTERIAN EYE, EAR AND THROAT CHARITY HOSPITAL OF BALTIMORE CITY.

Three years ago I read a paper before the ophthalmological section of the American Medical Association, on the value of 0.25 D. cylinder in the correction of the lesser grades of astigmatism. My additional experience confirms the position which I then took.

The annoyance occasioned by eye muscle strain demands recognition from complaining patients whose heads will ache when the eyes are much used. All astigmatic eyes do not suffer in like proportion. There are three factors at work that bring about annoyance. The first is the amount of eye work required by a badly shaped cornea; a second factor is the degree of fault; and a third is found in the nervous susceptibility of the patient.

As to the first condition, the amount of work required. The majority of astigmatic eyes only exhibit the trouble under forced application. Eyes which have done faithful and painless duty for many years are suddenly called upon for an unusual effort. They break down with pain, which then returns upon moderate use with a persistency that makes eye work unsatisfactory, and the individual miserable. The defect had always existed, and would not have been brought out had the additional labor not been undertaken. This is constantly illustrated in over worked advanced school children at examination periods. They complain of painful eyes and head from the too close application, when their parents, who exhibit the same degree of irregular refraction, have never suffered. This complaint is especially made if the young patient is of the nervous type, is rapidly growing, and is more anxious to secure good school grades than to take open air exercise. Hence girls suffer more than boys.

Physicians are seldom consulted by healthy people who have no physical complaints; and likewise ophthalmic surgeons only see those whose eyes are not comfortable. Such eyes are not necessarily inflamed; nor is there always dull vision. Most frequently the eyes themselves look in every way well, but with the inability to use them with comfort. The majority of those who consult me for painful eyes and head see clearly, and so state promptly: "It is not that my eyes are not sharp seeing, for I can see any small object that any one else can see, but they are not comfortable under use and my head aches when I read."

These two facts are daily noticed. So constant are they complained of that rarely do I not find irregular refraction when these symptoms are present, headache being the chief. My experience enables me to formulate, at least for my own guidance, this axiom: *Headache under eye use, with acute vision, in by far the majority of cases, means astigmatism, and usually of low degree.* If the irregularity of the cornea is not detected, it is because it has not been carefully sought for. It also means that the headache under eye use will not be relieved by any eradication or course of treatment until this irregularity of refraction is found and corrected.

Many specialists act upon the belief that V. $\frac{20}{20}$ is incompatible with annoying irregular curvatures in the cornea, and that it is needless to seek for astigmatism in such eyes. In cases of eye pain with acute vision their attention is therefore diverted from the true cause of the eye trouble to the examination for irregular action in the socket eye muscles, of which there is endless variety both in eyes that give no trouble and eyes that are painful. I find V. $\frac{20}{20}$ in one-third of my astigmatic cases; and this good vision among my most suffering patients. The most marked relief, and the most brilliant results from the adjustment of cylinder glasses I obtained among this class. Many of them had been under treatment by specialists and were wearing spherical lenses for near work but with no comfort. These cases are often mistaken for accommodative faults, formerly known as muscular asthenopia, and for which 1. + D. was the best known remedy. In former years I prescribed such glasses fifty times where I now have occasion to prescribe them once.

I often wonder what has become of the hosts of hyperopic eyes that I formerly saw and treated with spherical convex lenses. That I see the same character of eyes now I am quite sure, but no longer from the same standpoint. A more careful examination proves these cases to have been mild grades of astigmatism, often myopic. The same class still come to me from other specialists who are holding the views that I formerly acted upon, before I found out my mistake.

Years back I became aware that the most annoying irregularities of the cornea are the slight deviations, which are still compatible with sharp vision, V. $\frac{20}{20}$ or $\frac{20}{20}$, seldom less than $\frac{20}{20}$, and frequently the greater fault in one eye only. In my most ailing patients I so constantly find the lesser irregularities that I have been forced to the conclusion that in the high degrees of astigmatism the eye ceases to make the effort for acute vision, recognizing its inability; and hence the less muscular strain, and consequently less headache. In the small irregularities of corneal curvature, headache on eye use is the most constant and conspicuous symptom. It is more common than eye

ache although the two usually go together. When patients with refractive errors consult me complaining of defective sight and no pain in the head, as a rule astigmatism is either excessive or I find none of it. I accept as a most valuable aid in the search after astigmatism persistent headache on eye use. As I have previously said the reading of Jager No. 1, with V. $\frac{2}{30}$, by such patients are to me no evidences that a painful degree of astigmatism does not exist. With this acute vision patients with over-strained eye muscles often cannot read with comfort ten minutes, day-light even annoys, and fixation for a short time, as looking into the face of a friend while conversing or into the plate while eating, excites nausea.

In the casual examination of these patients, some of them at first see no difference in the tinting of the lines on the clock dial chart. They will repeatedly say, "I see no difference whatever, in the color. To me they are all exactly alike." This would look as if there was no astigmatism. After these repeated trials and assurance, most examiners would abandon the idea of irregular refraction. But I say to myself "here is a case of headache on eye use for near work. This patient, feeling well, can soon read herself into a headache. In my experience a low degree of astigmatism is by far the most painful source of this discomfort. I will continue my search until I feel assured that it does not exist." By perseverance in the examination of one eye at a time, I will eventually get out of the patient that all the clock dial lines are not exactly of the same tint. Some will now have a slight grayish, bluish or brownish tint, which was not perceptible at the first examination of the card. Once they detect the difference they never afterward lose it. Some lines now are not as clean black as other lines, and a weak cylinder will clear all up better than the duplicate number of a weak spherical lens. Some patients will persist in the statement that there is a uniformity in color for all the lines until homotropia is used, when the slight difference which is the cause of all the eye trouble is discovered. The adjustment and wearing of proper cylinders, 0.25 D. + or —, will promptly put an end to the eye and head discomforts which had been the torment of the patient for months or even years.

In my case book hundreds of such patients have been entered; persistent headache on eye use, the constant complaint; a low degree of astigmatism always found; a 0.25 D. cylinder prescribed with the result of treatment recorded at varying periods, days, weeks or months after the glasses had been given. "No headache since I have worn the glasses except on the occasion when I tried to read without them." By the wearing of these weak cylinders of 0.25 D., in numbers of cases patients have suddenly jumped

up from ten minutes reading with pain, to many hours continuous reading without any head discomfort whatever.

I will give but one illustration from among this very numerous class of recorded cases, because, on account of her professional history, it was of more than usual interest. The young lady was from New York City, was 18 years of age and well developed. She had been under more or less constant treatment on account of eye discomfort for five years, and had been removed from school because she could not study without pain in the head. When the first consulted ophthalmic surgeon who had her case under observation, had exhausted all theories and treatment with no relief, and had finally found weak recti muscles for which he advised tenotomy, the father refused to have any operation performed. The young lady, after an interval and still suffering, was put under the care of a second specialist. Guided by the experience of the first, as related by herself, he sought diligently to procure her relief. One by one all remedies were tried. Spherical lenses, practicing with prisms, internal medication, rest, but all with no benefit. When he had exhausted his resources he also suggested muscle cutting as the only untried remedy. He thought that relief would come surely through this surgical treatment. The father again declined to permit any operation. In the course of time this healthy looking girl, under blue glasses, was brought to my office for treatment. Her vision was $\frac{2}{30}$ and for one or two minutes she could read No. 1 of Jager. She was one of those who insisted that the test lines were all of uniform color, but she suffered with more or less constant headache. Under homotropia, horizontal lines seemed a little shady but not markedly so. Still she preferred a 0.25 + C.O. to a 0.25 + S in brightening up the entire face of the card. When the effects of the mydriatic had passed off, although the lines had again resumed their uniform brightness, she found relief in a 0.25 — C 90° rather than 0.25 + C.O. She was ordered the weak concave cylinder for constant wear. Before two weeks had passed by she could read for hours, night or day, with no discomfort whatever. Her headache returned whenever, for experiment's sake, she would put off her weak cylinder glasses, even for a short time. The relief from suffering was positive and permanent. I had a visit from the young lady one year after I had first seen and adjusted glasses for her. She still wore the weak cylinders and had no trouble whatever. She had resumed her education and as a diligent student was making up for lost time.

The necessity for recognizing the lesser degrees of astigmatism forces itself upon me daily. Long continued and persistent headache with eyes paining on use, uninfluenced by rest, medi-

cation, or hygienic influences, and relieved at once by a 0.25 D.C., ought to be proof enough of the necessity for discovering these low degrees of deviation from the true corneal curves. In many sensitive persons the verification of the diagnosis and the advantages of the treatment to the comfort of the individual are conspicuously shown when the cylinders are suddenly reversed. Pain and head discomfort seem immediately brought on by the mal-position of the axis of the lens. Then the restful condition when the cylinder is placed at the proper angle in the trial frame.

This 0.25 C. not only makes good vision easy, but often will make faulty vision good. All eyes needing a 0.25 C. have not necessarily $\frac{2}{3}$ V. Some exhibit only V. $\frac{2}{3}$, and yet this weak cylinder will enable them to see clearly the 20 line at 20 feet. This is curiously shown in eyes of the same individual which differ in visual acuteness, one eye may measure $\frac{2}{3}$ and the other only $\frac{2}{3}$ and yet each is made $\frac{2}{3}$ by the 0.25 cylinder. In another series of cases one eye will exhibit $\frac{2}{3}$ with all lines sharp, the other $\frac{2}{3}$ with one series of lines more distinct. The 0.25 C. will bring the dull eye sharply up to the normal, and the same glass will brighten up the whole picture when placed before the eye which without homatropia indicated no astigmatism. Should the cylinders be reversed, however, in the good eye irregularity in the blackness of the lines would at once show itself, in evidence that the small degree of fault was being concealed by the eye muscles. It would come out, in spite of muscular effort to the contrary, when the fault was doubled by the wrong position of the cylinder.

I daily see persons who, in giving their history, can fix the time from which their head and eye discomforts started. Up to a certain period they had used their eyes with comfort. Then came a sudden demand for closer application and with it the trouble commenced. As the astigmatism is usually a congenital fault, it must have always existed, therefore, notwithstanding the astigmatism, the eyes had been comfortably used in moderation. We also often find that when some extra work had increased the eye strain and made the head ache, the rest given by the temporary wearing of a cylinder would in time enable the astigmatic eye to do without the spectacle provided no unusual eye effort be again made. With young ladies it is no uncommon occurrence to find cylinders discarded at the end of school life, at least by those with whom the demands of society allow no time for close eye work.

We consider the shape of the eye ball as much a feature to be inherited as the shape of the ear, nose or mouth, with this important difference, that whether the nose is pointed or stumped we can smell with it equally well, but should any deviation occur from the typical shape of the eye

ball, interference with vision is the consequence. These deviations in the eye shape are the rule. A perfectly formed eye in these days is as much an exception to the typical shape as a beautiful face is to the average citizen. Hence it is that I find astigmatism extremely common. With those who must apply themselves to close work, it is the common cause of head discomforts, which can only be relieved by rest, and this class can not afford it, or by the wearing of cylinders, which is now within the reach of everyone.

We often find a patient prompt in accepting or rejecting one of two cylinders that differ in strength a 0.25 D. There are some ophthalmic surgeons who will permit an eye to vary from a 0.5 to 0.75 and know that they are giving an immense degree of comfort to their patients by recognizing this difference. These very surgeons repudiate the ability of an eye to determine between a 0.5 and 0.25. The eye accepts the 0.25 C. but the surgeons have drawn the line of the 0.5 C., and avow they will never prescribe a glass that is weaker. The result is that some one else will have to do it. I find myself applied to by persons coming from other specialists with the 0.5 D.C. with head discomforts unrelieved, who secure freedom from headache and the ability to use their eyes with comfort when the cylinder has been reduced to 0.25. I so often find the use of a 0.25 D.C. making the difference to the wearer of from not being able to read a few minutes without headache to reading for hours with no headache, that I expect to secure these good results in prescribing them.

Another very common experience with me is that persons who suffer with persistent headache and hardly remember the day that they have been free from it, secure relief from the day that the 0.25 D.C. was first put on.

In the last four years I have been using the 0.25 D.C. more and more frequently. To give some idea of the number of 0.25 D.C. which I prescribe I find that last year alone I gave them to over three hundred private patients, and in hospital practice to fully as many more, so that in one year over six hundred pairs of 0.25 C. have been prescribed through myself alone. The uninitiated would say that in many of these cases the glasses must have amounted to nothing. That suggestion is promptly met by this counter-statement, all of these persons, mostly young students, bookkeepers or sewing girls, suffered more or less severely with headache and eye pains on eye use and they had applied for special treatment with the hope of getting rid of their annoyance. As with them all close application was a necessity, they all suffered from their daily work.

In all of these a small degree of astigmatism was found, which a 0.25 C. D. completely corrected. The fault was most frequently in the horizontal meridian, next in frequency in the

vertical and least frequently in the oblique diameters of the cornea. As a rule the annoyances were greatest when the faulty corneal curvatures were obliquely placed. The 0.25 C. gave the relief sought, in by far the majority of these cases. In many of these persons whose history could be traced, perfect relief continued with the use of these weak cylinders.

I have formulated for myself in office work this order. When a young person with no eye congestion who has $\frac{20}{20}$ vision and reads readily No. 1 of the test types, complains of pain in eyes and head on use, so convinced am I that astigmatism is at the bottom of the trouble that I seek it at once, in the very beginning of the eye examination. If it had not been found by others it is not because it did not exist, but because it had not been diligently sought. That a great many of these patients would exhibit heterophoria from the fixed standard of muscular strength, I am quite convinced. I find in by far the majority of cases with the correction of the astigmatism all evidence of muscle straining passes off, and in such patients the heterophoria does not call for recognition, because it no longer annoys when the cylinders are worn.

The least degrees of astigmatism cause in the world the greatest amount of head and eye discomfort, and the 0.25 C. will correct these refractive errors and will relieve head and eye pains. I not only therefore say that the weak cylinder ought to be prescribed, but that the ophthalmic surgeon is remiss who does not seek, find, and correct these small but annoying errors in corneal curvature.

DISCUSSION.

DR. J. L. THOMPSON spoke of a case in which 0.25 D. gave relief when 0.50 D. did not.

DR. F. C. HOTZ said he often finds cases of a low degree where cylinders do not relieve the asthenopia. In these cases the asthenopia is due to heterophoria.

DR. T. E. MURRELL called attention to an unaccountable condition frequently observed by him, viz.: two eyes having an equal degree of astigmatism but with very unlike vision uncorrected, one being sometimes doubly as acute as the other, but both having equal vision with the same correcting glass.

DR. GEORGE T. STEVENS: There appears to be no difference of opinion in respect to the correction of practical degrees of astigmatism. The question is, what constitutes a practical degree of astigmatism? The judgement of the surgeon must determine whether an amount of astigmatism bordering upon perfect or practically perfect refraction is to be regarded as an amount which will require the use of glasses which by their mechanical objections are irksome to the patient.

The physical condition of the patient, the form of astigmatism, and various conditions must guide us in determining the prosperity of a constant correction of vary minute degrees of astigmatism.

DR. BURNETT, of Washington, said the normal astigmatism was at least 0.25, but that undoubtedly the wearing of a 0.25 cylinder would often give relief to asthenopic symptoms. In these cases he thought the astigmatism was somewhere between 0.25 and 0.5. He was interested in the statement of Dr. Chisholm that version had in one instance been advanced from $\frac{20}{50}$ to $\frac{20}{20}$ by means of a 0.25 cylinder. He could not consider it as physically possible. There must have been some mental astigmatism.

MONOCULAR DIPLOPIA.

Read in the Section on Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY I. H. THOMPSON, M.D.,
OF KANSAS CITY, MO.

The relation between the eye and brain has always been a fascinating subject for study, and as would be naturally expected, the school of ophthalmology has done very much to aid in the determination of the characters, symptoms and localization of cerebral troubles. The invention of the ophthalmoscope antedates but a short time the development of the cerebral surgeon, and although this instrument enables us to almost see the brain, it can only yet be considered an aid to diagnosis, for the knowledge we have of cerebral morphology is the result of the patient study of many minds and the sifted records of ten thousand cases. Every addition to the common fund of experience may be of value to all, so I feel that I am justified to introduce the subject diplopia monocularis, with a report of a case from my own practice, and review some cases from the writings of others. They are few and scattered, but they all refer to monocular diplopia dependent upon intercranial disturbances, and in no way the result of interocular disease or refractive error. My purpose in the preparation of this paper is to speculate on the cause of this remarkable symptom, and to try and find why it has been put down by certain chirurgical authorities as one of the signs of brain tumor. Whether monocular diplopia is a common occurrence or not, I am unable to say. My own experience is limited, but the fact that so little has been written about it by ophthalmic surgeons, leads me to believe that, as a symptom of nervous disease, it is rare or often overlooked. The following case is remarkable and of more than common interest:

Miss T., a healthy, moderately robust lady, 35 years old, was injured in a railroad accident on the 25th of July, 1890. She was sitting in a

chair car when the train, which was moving very rapidly, left the rails. The car turned half over and was thrown against an embankment. Although she was expecting to be hurt, and for that reason held fast to her chair, she was thrown completely down the car into the opposite corner. She was for the moment stunned, but rapidly recovered and, assisted by the porter, left the car. She received a slight cut over the left fronto-temporal region; she had no other wounds of the head, so after the bleeding stopped she walked around, attended to herself and conversed with the passengers. She took a relief train home, and went to bed. The next day she was sore from the bruises she had received, and found that she had a fracture of the coccyx. Because of the tenderness of the spine and sacrum she remained in bed four months; she was then able to sit up some little, and on several occasions went down town. On one of these trips she visited me. She complained of diplopia, which had lately come on, and which so annoyed her that she could not walk steadily or use the eyes at very close work, unless she bandaged one with a handkerchief.

I examined her eyes and found them slightly astigmatic. With each eye tested separately, and aided by the correcting cylinder, vision was normal; she had pronounced homonymous diplopia—the flame seen by the left eye was to the left and above the one seen by the right; the two flames could be brought on the vertical line by moving the candle to the right, but they could not be united without prisms. Pupil reaction normal, no color blindness. On pressure, the scar of the wound of the head was tender; no other symptom whatever of cerebral irritation. The diagnosis was simple myopic astigmatism $\frac{1}{2}$ dioptre; paresis of the left external rectus and left inferior rectus, probably dependent upon injury of the head or spine. I saw her twice, and recorded no change in the condition.

In the meantime she entered suit against the railroad company for damages. I was summoned by her to testify, but refused to go into court as an expert without an extra examination.

At this examination I recorded monocular diplopia, and although I was suspicious, still, after a most careful trial with prisms, I was compelled to admit that she had not only homonymous diplopia, but also diplopia in each eye. When, in a darkened room, she looked at a lighted candle, she saw four distinct flames, and if a prism, base downwards, was moved before one eye, the moment the apex entered the pupil area she saw six flames. The same phenomenon was observed when the other eye was armed with a prism. In each eye tested separately she was double. In an endeavor to measure the parietic deviation, I was embarrassed by the inability of the patient to define the relative positions of the flames, which was further augmented by the fatigue the trial

occasioned. There was a strong probability that the insufficiency of the left external rectus and superior rectus still existed in its original degree. Regarding the monocular diplopia I made the following note: Left eye examined, right covered, dark room, lighted candle at 20 feet, diplopia, flames diagonally opposite each other about 18 inches apart. Each light was equally distinct. A black dot on a piece of white paper, at reading distance, was seen double, diagonal diplopia; a black pencil $\frac{1}{4}$ inches long, held vertical before the eye at 16 inches, was seen double, lateral displacement; held horizontal, double, horizontal displacement. When the pencil was tilted from the vertical to the right, the two objects approached, and at 45° —degree calculated as in fitting cylinders—the pencils were united, the patient described the picture as one pencil covering the other, the inner being nearest to her and projecting somewhat over the other. Beyond the diplopia and appreciable contraction of the visual field, the eye was normal, vision with cylinder -0.5 $180^\circ \frac{2}{3}$. The right eye was examined in the same manner, the same diplopia, four lights, with the edge of the prism dividing the pupil; the same angle and relative distance of displacement. When this eye was examined with the pencil the same phenomena were observed as in the left, at exactly 45° the pencils united. When first tested, this eye had normal vision, but at the last examination vision had dropped to $\frac{2}{3}$, with the visual field very much contracted. Pupil reaction normal, no appreciable disease of the fundus. Suspecting that there may have been some organic lesion of the brain to account for such symptoms, I carefully sought for the different kinds of aphasia, word-blindness, etc., but could find no apparent disease whatever.

To my mind this was a case of hysteria, that the paresis of the recti muscles was of the character named by the French *hystero-traumatique*, and the monocular diplopia was the immediate result of autosuggestion. I so stated on the stand. Of course there is a possibility that the binocular diplopia first complained of referred in some way to functional derangement of the nerve centres. It certainly was not the result of nuclear paralysis, and a cortical lesion as the determining cause may with equal certainty be discarded. There are many reasons to believe that this symptom is in the majority of cases hysterical. To support my opinion, I beg leave to present a translation of a similar case reported by Brunschwig in the *Recueil d'Ophthalmologie*, August, 1889:

Leonie L., age 11 years, had for six years a converging squint of the right eye; had never had disease of the eyes. Suffered at 10 years of age from an attack of typhoid fever. We first saw the patient on the 3d of August, 1889, when we were asked to straighten the eyes. By oblique illumination and through a lens we could see that

there were two small nebulous deposits in the cornea, tending to a V-shape, but the ends were not united. The iris was normal, no ophthalmoscopic lesion. Both eyes were hypermetropic 3 dioptres, also some astigmatism, but correction of the refraction did not very much improve the vision. Good perception of color by both eyes. The visual field is notably contracted, especially that of the right eye, whether tested by white or colored objects. An object viewed by the right eye is seen double; when a rod of red sealing-wax was held vertical before the eye at 1 metre distance, the patient saw two rods, lateral displacement about 5 centimetres and parallel. At 4 metres the objects were double and parallel, the two rods remaining about the same distance apart whatever distance they were away. If the rod was placed horizontal before the eye, it was seen double, vertical displacement, parallel and 5 centimetres distant. In whatever position the rod was held before the eye, it was seen double. The correction of the hypermetropia and the astigmatism had no effect on the diplopia, nor on the distance between the two images. A prism 10° placed horizontal before the right eye, the left being closed, gave a picture of four objects when the base divided the pupil area. The rod viewed with both eyes is seen triple, which lasts but a moment, for the squinting eye immediately returns to its false position. A stereoscopic examination did not in any way change the result, but when the patient viewed an object through a boise-de-Flees, it was found that the diplopia could be transferred to the left eye, if the patient believed the trial only referred to the vision of the right.

The author, in commenting upon this case, speaks decidedly in favor of an hysterical hypothesis, for, as he very properly remarks, what abnormal condition of the brain could bring about such a train of symptoms without other evidences of organic disease? Of course the last test and proof of simulation, made by the examination with the boise-de-Flees, was conclusive, and fixed decidedly the nervous nature of the complaint. In the light of our present knowledge of the hypnotic influence, we are prepared to believe that many more strange and remarkable perversions of the intellect are possible than have heretofore been supposed, and for convenience we place them all under the symptomatology of hysteria. We know that in certain mental conditions the phenomenon autosuggestion is easily excited, and is it not probable that its relation to the simple reflex movements is closer than neurologists are prepared to admit?

This may in a measure account for that peculiar symptom, monocular diplopia, which in the cases above referred to, was so prominent. In the child we had the squint, and therefore supposed diplopia, which was immediately referred

or transferred to the right eye when, in an endeavor to measure the refraction of that eye, the attention was directed to the right visual field.

There are several circumstances which lead me to think that a like cause had a similar effect in my own case. The primary parietic squint and its necessary diplopia excited in a disturbed brain, an impression which culminated in a true visual hallucination.

I find several similar cases reported, two by Hayfelder in 1849. Both subjects were watchmakers; they recovered. Notice! That watchmakers learn to suppress the usual field of one eye; when working with a lens the near point is brought within the range of convergence.

Foutan, in 1885, reported to the Ophthalmological Congress the case of a boy 14 years old, a subject of monocular diplopia without ocular disease, but a true neurotic. Foutan, in commenting upon this case, suggests the following, which Brunschwig publishes, but questions: "The image formed on the macula is received normally by the nerve which divides at the chiasma, so that two similar impressions are conveyed to the corpora quadrigemina, or implanted on the visual centres at the cortex. Ordinarily the two pictures are united by a cerebral act or sympathy, which exists between the functions of the two brains. If, however, the joining of the two pictures does not immediately take place diplopia is the result." Should, because of functional disease or interference with the normal conduction of impulses or nerve discharges along certain established paths throughout and between the hemispheres, the personal equation of either brain be shortened or prolonged, there can arise a condition about the visual centre at the cortex analogous to parietic squint, or what the ologists call diplakousis. Therefore, I am inclined to the opinion that there is more in Foutan's theory than is commonly believed, and that in such cases the trouble lies in a lack of harmony between the two visual centres.

James E. Adams reported to the London Ophthalmological Society a case of monocular diplopia. A woman injured in a wreck, suffered from converging strabismus and monocular double vision which lasted several weeks. The trouble was referred to the right eye, in which there was no disease of the cornea or media. She received damages and then rapidly recovered; diagnosis, hysteria. Dr. Ord, *St. Thomas Hospital Reports*, 1879, case of boy 13 years old. An epileptic, could find nothing abnormal in the eye or brain.

In the opening paragraph of the report of a case of monocular diplopia, published by Sucamis in *Zahenders' Monatsblätter für Augenheilkunde*, July, 1890, the author states that the diplopia has been recognized as one of the symptoms of

intercranial tumor. This is undoubtedly true, but after a careful perusal of the literature of brain lesions I am able to find but very few well authenticated examples, and they principally in recent publications. The most instructive case is one reported by Dr. Shaw, of St. Louis, in the *Kansas City Medical Record*: Chas. Green, a Scotchman, laborer, good family history, of sober habits; received a blow from a crowbar on the head eight years ago which rendered him unconscious for some time. He remained well until the summer of 1890, when he was attacked with vertigo and severe pain in the head. The headache became constant; he then developed symptoms of tumor of the brain, in staggering gait, vertigo, straddling walk, pain in the head, deafness of the left ear, right homonymous hemiopia and diplopia of the left eye, double optic neuritis, vomiting and epileptic attacks. The left ear began to discharge a short time before he was admitted to the hospital, but before that he had had a lump behind the ear which had been lanced twice. He never had earache. He died. The author, in reviewing the symptoms, had no doubt but that he had a case of brain tumor. The symptoms suggested either tumor or abscess; but the lack of fever, sweating, and evidence of inflaming before the ear discharged, rather excluded a probability of cerebral abscess and confirmed the opinion expressed. By an ingenious reasoning Shaw located a tumor in the cerebellum, immediately under the tentorium, probably pressing against the occipital lobe. Being anxious to complete the report of the case, I received of Dr. Dalton a copy of the Records of the City Hospital of St. Louis:

"Charlie Green was admitted to this institution Oct. 3, 1889, and died April 18, 1890. From him we learned that his family history was good so far as he knew. His father and mother died when he was quite young. He himself had never been seriously sick, but at one time or another he had all of his limbs broken. He was never addicted to drink. For some months before admission to the hospital, he had shooting pains in his head in the morning while lying down, but had no trouble when walking about. He has had, and has now an eruption on his hands, face, forehead, shoulder, and anterior portion of the thorax. It began on his chin, and had existed about one year. No history of syphilis could be made out. November 4, he informed us, for the first time, that he had received a blow on the top of his head eight years before; he was unconscious for awhile, after which he had no trouble. Four months before admission to the hospital he first noticed the present trouble. While working one day he suddenly became dizzy and remained so for ten or fifteen minutes; this was followed by terrible

pain in the head, mostly at the base of the brain and about the occiput; pain remained several hours and then disappeared. The next day he had a similar attack; the attacks have been quite frequent since that time. The first sensation was a rush of blood to the head, then dizziness followed by severe pain, sometimes shooting in character, at other times dull. The attacks would usually last about two hours, and come on four or five times a week. He never became unconscious or delirious. During the last three months he has been very restless at night; talked a great deal in his sleep. His business had been that of a moulder, which he had to give up, because he was unable to stoop without causing a return of the headache. On October 10, a week after admission to the hospital, he was found standing in the watercloset in an unconscious condition, looking wildly around. He was gotten to bed with great difficulty, where he lay muttering and holding his hands to the side of his head. Pupils dilated; too restless to determine their reaction; heart active, though weak and irregular; face and lips pale. After a few hours returned to consciousness; stupid headache very severe; pulse weak; urine normal.

November 5. Patient complains of the pain in the head, especially at the base of the brain; this condition now remains almost constant. Attempts to wander around the wards in an aimless manner, with difficulty kept in bed. Was given large doses of the iodide of potash, without benefit. On January 6 a few epileptic attacks were noted, and these were preceded and followed by severe headache, which would always begin in the posterior and lower portion of the head, and soon pass over the entire skull. This was accompanied by dizziness. He always fell on his left side, and in walking during these attacks he always walked to the left. Hearing in the left ear defective, left eye amblyopic. He sees double with this eye always, sometimes also with the right eye. He has right hemianopsia, sometimes the entire field is narrowed. On the 2d of March he had a severe fit, followed by intense headache; this condition continued about the same until April 8, when he died in a convulsion.

The post-mortem examination showed all the organs normal except the brain. On opening the calvarium a large quantity of cerebro-spinal fluid escaped. In the right lobe of the cerebellum was found a cyst holding perhaps half an ounce of fluid, and a tumor about the size of a small lemon. The growth extended up into the right peduncle."

Another very interesting and well prepared case is reported by Dr. Tilley, of Chicago, in the *American Journal of Ophthalmology*, January, 1888:

"Mary R., 9 years old, orphan, was presented to Dr. Tilley suffering from a peculiar train of symptoms. Her face had the appearance of her

being in great distress, and she held her head as if she was afraid of jarring it; spasmodic ptosis; she complained of some infra-orbital pain, which was increased by pressure; she also had pain on lateral movements of the eyes, so that she moved the head in looking sideways. There was no paralysis or paresis of any of the muscles. She suffered from headache which came on every day. No malaria. Conjunctiva slightly congested, lids, cornea, lens, vitreous and retina normal. Vision $\frac{6}{78}$, pupils normal and reaction normal. She complained of double vision in the left eye. A probe held vertical before her was seen double, horizontal displacement; held horizontal, double, vertical displacement. A most careful examination to detect fraud, convinced the doctor that her statements were true. At all parts of the visual field diplopia was present, the distance between the two images corresponded with the distance the object was from the eye. The sign of the interocular angle increased as the visual line was lengthened—at 1 metre the displacement at the retina was .074 millimetre, at 6 metres about .456 millimetre. Paralysis of the accommodation by atropia made little difference in the subjective phenomena, but the secondary image appeared nearer. The patient was completely red-blind. These observations were made during November and December, 1887. On the 13th of December, the girl had symptoms of cerebral disease; vomiting, delirium, etc. The child improved. Dr. Tilley visited his case in January, 1888, and found her suffering from abscesses all over the body, which inclined him to believe that at one time there had been an abscess of the cerebrum encroaching upon the lateral ventricle."

John Abercrombie, in 1881, reported a case of a girl suffering from headache, vomiting, peculiarities of speech, paralysis of the right side, with paralysis of the right external rectus. She had double monocular diplopia. On post-mortem examination, found a large abscess in the left occipital lobe and rupture into the ventricle.

The three above cases are well-marked examples of diplopia monocularis dependent upon intracranial disease. In Abercrombie's case we find an abscess of the right occipito-temporal lobe. Of course the extensive disease of the brain substance and membranes, together with the ventricular empyema, was undoubtedly the cause of death, but this was the sequence of an inflammation starting in the occipital lobe which affected (not involved) the right cuneus and optic tract, by pressure or irritation. Although it is extremely difficult to determine the relation between cause and effect, the paralysis of the external rectus depended upon an inflammation at the base involving the sixth nerve in its course, and not nuclear. It may be asked, if this reasoning is correct, why was there now left homonymous hemiopia? I think the seat of the abscess was

too far from the cuneus to immediately destroy that visual centre, but sufficiently near to embarrass it. In the Tilley case, the author was inclined to locate the trouble near the third ventricle, but he candidly admits his inability to explain the sequence from cause to effect. The symptoms were unquestionably cerebral, and probably the cause was an abscess deep in the substance of the left occipital lobe.

The Shaw case is both interesting and instructive. The diplopia monocularis was one of the principal symptoms. That there was direct pressure and disturbance of the visual centres is demonstrated by the post-mortem. A tumor of the right cerebellum, of the character and size found in the autopsy, could hardly exist without distending the tentorium and pushing aside the posterior convolutions of the occipital lobes. Although I can understand the sequence of symptoms in this case, I can hardly explain the right hemiopia unless there is a mistake in terms. The choked discs could account for the narrowing of the visual fields, but not the hemiopia. It is evident, therefore, that the lesion was at the visual centres, and inasmuch as the diplopia could not have been recognized if the object was focused on the blind area of the retina, the irritation or cause of the phenomenon must have been at the visual centre least affected by the disease, viz.: the left cuneus. I have grave doubts if the so-called papili can occur unless there is some obstruction about the venous sinuses. Putting aside Seber's theory of the inflammation of the nerve caused by the presence in the vaginal sheath of irritating material, it is hard to explain the hypertrusion of the arachnoid fluids without admitting the probability of venous obstruction. Therefore, I am led to think that a lumen in the cerebellum large enough to interfere with the return of blood through the lateral sinuses, could very well paralyze by pressure the terminal occipital convolution, and involve the cuneus. This may explain the relative rareness of monocular diplopia. Hemiopia from tumor or abscess in the occipital lobes is common, associated with choked disc and amblyopia, when the diplopic symptom, which under different circumstances would be apparent, is marked. I think that monocular diplopia more often exists, but is overlooked. In nearly all, at least the majority, of the cases reported, this symptom was seen in connection with paralysis of the sixth nerve, a peculiar and remarkable coincidence. It is hardly reasonable to suppose that an individual suffering from extensive tumor or abscess of the brain would be in a condition to notice a visual peculiarity of this kind, unless by chance the attention was stimulated by an extraordinary examination. The history of the cases at our disposal, those reported by Shaw, Tilley, Abercrombie and others, is an evidence that double vision, confined to

one eye, is not so rare as has heretofore been supposed. My conclusions are:

1. Diplopia monocularis is, in the majority of cases, one of the symptoms of hysteria, provided there are no physical conditions in the eye which can cause an object to be focused on two spots of the retina at the same time.

2. Diplopia monocularis in connection with recent or old squint, paralytic, hysterical or otherwise, is a symptom of a psychical condition, closely related to hysteria, in which the phenomenon, autosuggestion, is easily excited.

3. Diplopia monocularis not dependent upon disease or abnormality in the eye, but in connection with other symptoms of intracranial trouble, especially choked disc, hemiopia, paralysis, particularly when the train of symptoms points to tumor or abscess, is strong evidence that the lesion is situated in or about the posterior convolution of the occipital lobes.

AN EXAMINATION OF VON GRAEFE'S DOCTRINE OF "ANTIPATHY TO SINGLE VISION."

Read in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY GEORGE T. STEVENS, M.D.,
OF NEW YORK.

In Von Graefe's classical description of the condition to which he applies the term "Antipathy to Single Vision," he says: "It has sometimes happened to me that after squint operations with apparently correctly adjusted visual axes there have resulted double images only slightly removed from each other. The visual power of each eye has been quite good, alternating strabismus having previously existed, and the accommodative power has been similar in the two eyes. Nevertheless it has been in no way possible to bring about single vision."

He states that this condition of double seeing persists notwithstanding the interposition of prisms in various positions, and that every effort of the patient to unite the images results only in removing them to still greater distances.

He adds: "The tendency appears to be a direct physiological contradiction; for while in sound eyes some approach, especially in case of large retinal pictures, is sufficient to induce arbitrary muscular contraction in the interest of single vision, in these cases, on the other hand, it is found that exactly the opposite condition prevails, there being an absolute incompatibility to single vision."¹

In a still later article² he describes the condition more at length, pointing out the fact that the double images, although not far removed,

pass from one side to the other, above and below, or one behind the other, always on the point of uniting, but never united. Von Graefe explains the anomaly on the theory, first, of injury to the nervous centres of faulty projection from the retina, and, second, of the supposed difficulty of obtaining regular associated action between muscles which have long been unaccustomed to association.

A careful examination of many of these cases of "antipathy to single vision" leads me to conclusions different from those arrived at by Von Graefe, and the practical application of these conclusions has shown that they are, at least in a great measure, correct. That, in a proportion of these cases, the technical details of disturbing elements may elude our search is undoubtedly true, but that the principles which I shall present will apply very generally I am fully convinced.

In a paper read before the American Medical Association, June, 1889,³ I have already expressed my disbelief in the generally accepted view of the existence of a physiological antipathy to single vision, and my conviction that, by properly selected and properly executed proceedings, this unpleasant condition may usually be eliminated.

The view of the causation of this anomaly, as set forth in that paper, may be briefly condensed into a single sentence.

The condition of antipathy to single vision as described by Graefe and by subsequent authors depends not upon lesion of the brain or faulty projection of the images from the retina, but upon unequal tension of corresponding ocular muscles under the influence of corresponding nerve impulses directed to them.

I do not assert that no irregularity in projection from the retina can occur, nor that cerebral lesions may not induce incorrigible diplopia. Such cases, if found, will present other and more definite phenomena of the existing ocular or central nervous disease than simply the presence of diplopia. The proposition refers to the cases which come fairly within the class so clearly described and so sharply defined by Graefe.

Excluding then, cases of paresis, and confining ourselves to the class of cases thus defined, we shall find the causation of this supposed antipathy mainly in two conditions. The first of these is acquired as the result of the squint operation or operations. It consists in the fact that by unequal settings back of the insertion of the corresponding tendons, there are induced irregular responses to the impulses directed to these corresponding muscles. In the examination of a very large number of cases, I have found this condition, but generally modified by a second to be mentioned presently, by far the most preva-

¹ Arch. für Ophthalmologie, i. 1, 118.

² Arch. für Ophthalmologie, iii., 1, 119.

³ Published in Archives of Ophthalmology, vol. xviii., p. 371.

lent. There will be found in such cases either an excessive rotating power, or a power of rotation only moderately restricted, of the muscle of one eye, internal or external rectus, while the rotating power of its direct associate of the other eye is materially restricted. As a consequence of this irregular and unequally balanced condition of opposing muscles no harmonious adjustments can be made, and the more earnestly the patient strives to bring about associated action, the more signally he fails.

That "settings back" of the ocular muscles to an unequal extent may be made with propriety and with success, was taught by the great master, Von Graefe, himself, and the practice has been very generally continued to the present time.

It is true that Von Graefe advised in extreme cases a division of the operation between the two eyes, but in fact, this was a concession only to most obvious disabilities involved in the failure of the most conspicuously associated movements toward the side opposite the eye operated on, if in a case of converging strabismus, and an impediment to even approximate convergence at near points. Within the limits of extreme results a full correction of the appearance of squint was, according to his teaching, not only permissible but desirable. This proceeding of making a correction of squint by a single operation has been supposed to be sustained by the theory that the muscle of the squinting eye is pathologically shortened to a considerably greater extent than its antagonist.

It may be conceded that there is, within certain limits of unequal tensions of accordant muscles, a possibility of union of images; otherwise binocular vision would in no case be established except when exact balancing of the tension is secured. That easy and permanent associated action is compatible with any considerable degree of diversity of tension, I do not believe.

It may be objected that if this proposition is correct the proportion of perfect corrections for squint by the prevailing methods of operating must be less than is ordinarily supposed. It is probable that examinations made by methods more exact than those which have been ordinarily employed would show that a very large proportion of cases in which binocular vision has been presumed to have been established by the ordinary squint operation is much smaller than is commonly supposed. However this may be, whether the results of the standard squint operation is often successful or not, it is certain that such unequal tensions are in many instances incompatible with a blending of the images.

A second causative influence, and one which acts as an element in nearly all of these cases, is

the difference in relative tension of muscles which act in the vertical direction.

The instinct of bringing images to the same horizontal plane appears to be very great and only second, if indeed it is second, to that of union of images. In case of double images, whatever the difficulty of blending may be, the patient instinctively exerts his best endeavors to place the images in the same horizontal plane. It thus happens, that in certain cases in which, either with or without slight lateral inequality of tension, the effort to bring images to the same plane induces a lateral squint,—a squint which may be variable; that is, such a squint may at one period of life be converging, and at another diverging. Thus, in a case now under my observation, the patient was, during her childhood, subject to a very pronounced converging squint. During the past twenty years she has had conspicuous diverging squint, although no opera-

FIGURE 1.

tion has been made. Such a condition may properly be called *variable strabismus*, its character of divergence or convergence changing from time to time, remaining possibly in one direction during several years, then changing to the opposite direction.

If in such a case one or both interni or externi are cut, double vision of an intractable form is likely to result. In such cases we must make diligent search for the vertical deviation, a condition often obscure or not at all manifest, before we can succeed in establishing binocular vision.

I have had the good fortune to obtain a daguerreotype portrait of the lady whose case has just been mentioned, taken during her childhood, and from which I have made an enlarged photograph which I have the pleasure of show-

ing (Fig. 1). The photograph shows converging squint, so pronounced that few ophthalmic surgeons even at the present day would hesitate in regarding it as a proper case for a free division of the internus of one, if not of both eyes. Had such an operation been performed upon this patient in early life, intractable diplopia would doubtless have resulted, and eventually extreme diverging strabismus. In another photographic portrait of this lady, made by myself a year ago (Fig. 2), a moderate appearance of diverg-

FIGURE 2.

ing strabismus is seen. In fact a divergence of more than 12° with corresponding crossed diplopia existed. But the most striking feature suggested by this photograph is the left hypertropia, well defined in the position of the eyes and of the brows. The question at once arises whether the change from converging to diverging strabismus is not the result of some radical change in the static condition of the eye-muscles. That this is not the case will be seen by the most cursory glance at the third portrait (Fig. 3), in which the old converging squint has returned. This condition of convergence can be induced at

FIGURE 3.

any time by the application of a solution of atropine to the eyes. At the time of taking this third portrait, atropine had been applied twice a day for three successive days, and its effects were complete. A week after that time the diverging squint had returned and has continued during the year. The transformation from divergence to convergence occurs within an hour after the first application of the atropine, and the present habitual condition of divergence returns as soon as the effect of the drug passes off. This variability is, without doubt, due to the action of the muscles in the effort to overcome the unequal height of the images, and until the condi-

tion of the hypertropia is eliminated such changes of the lateral relations are liable to occur. In passing, a single thought may be given to the adverse testimony of such cases to the well-known doctrine of the relations between the excessive efforts at accommodation and converging strabismus; for here the converging strabismus occurs only when accommodation is neutralized. The present interest in the case centres in the fact that had a free tenotomy of an internus been practiced during childhood, the almost certain result would have been an "antipathy to single vision." Even at the present time, when the conditions of hyperphoria and hypertropia are carefully sought for, this patient is able, under many circumstances, to conceal completely the evidence of hyperphoria as shown by the phorometer.

FIGURE 4.

A curious fact in connection with the inequality of tension of the lateral muscles associated with hyperphoria is, that a condition which in a passive state of the muscles of either eye or of both eyes is a marked divergence, becomes, as soon as all the muscles are engaged in the act of adjustment, pronounced convergence attended by homonymous diplopia. Conversely a like change may occur when the tendency is, in the passive state, to converge.

A very practical illustration of what has been stated may be found in an actual history which I condense for this purpose. In a child with left hyperphoria (or hypertropia) the left eye drifted outward during the first few years of life. (Such a diverging squint is rarely observed by parents unless it is extreme.) At length, presumably as the result of a change in the methods of making the efforts to adjust for the horizontal plane, the squint became convergent. The ap-

pearance of the eyes of this patient in early childhood is represented in Fig. 4, which is copied and enlarged from a daguerreotype picture of him taken at the age of about three years.

About three or four years later, and after the divergence had given place to convergence, a surgeon performed tenotomies of the two recti interni, presumably severing both tendons completely. The result proving an over-correction, the effect of the operation on one eye was modified by the insertion of a (conjunctival?) suture. The result, in view of what has been stated above, was such as we might anticipate. Double vision of the most annoying character was always present. The efforts of many distinguished surgeons to induce these twin images to unite by means of prisms, even for an instant, were fruitless after trials repeated during many years. The case found a prominent place in ophthalmological literature, endorsed by several distinguished surgeons, as one of the class now under discussion. No case could therefore afford us a better model for our study.

It proved easier for this patient to fix objects with the left eye. That being the case, we may suppose that he would make a certain effort of adjustment with the weakened internus of that eye, which would be associated with a corresponding excessive effort of the opposite internus. But these unequal efforts would also be combined with the effort to adjust for the difference in the positions of the images with reference to the horizontal plane. The result would be an excessive rotation of the right eye to the nasal side with homonymous double images. If, on the other hand, a patient with this combination of defects should look at an object which is isolated from other objects which may serve to aid the disabled eye in active adjustment, as, for instance, at a church spire, or at the moon, or a bright star, in which cases only the clear sky is in immediate relation to the object, the most disabled eye would at once drift outward, and crossed diplopia would result. So also, if a small screen were to be interposed between either eye and the object looked at, thus shutting it out from active participation in the effort of adjustment, the covered eye would diverge in a marked manner and would move inward, perhaps to the extent of one third the diameter of the cornea, as soon as the screen should be removed, and then homonymous diplopia would be observed. Or again, if the subject of such a defect were to look through a grating, as, for instance, through the palings of a picket fence, an object seen beyond the fence would be seen doubled, and the diplopia would be crossed; while an object seen between the person and the fence would be double also, but the double images would be homonymous. In the first instance, looking beyond the fence, the adjusting energy of one eye becomes passive, as

in the case of looking at the object against the clear sky, with resulting crossed diplopia. In the other instance, looking at the object nearer than the fence, active adjustment of both eyes occurs with excessive convergence and homonymous double images. All these suppositions and conclusions have been fully justified in the actual treatment of these cases.

In certain cases in which this intractable diplopia exists, the patient has the extraordinary faculty of selecting at will which eye shall fix the object, and the diplopia becomes homonymous or crossed, according as the one or the other eye is engaged in direct fixation. Thus, in the case of a lady patient, if I direct her to look with the right eye, I can see that the eyes are strongly converged, and she reports the presence of homonymous double images. If I then direct her to look with the left eye, the change may require a few seconds or it may take place very quickly. Then the eyes are plainly seen to diverge, and the diplopia is crossed. In such a case, the nervous impulse directed to the right internus is greater than the normal during fixation with that eye, and when a corresponding impulse is sent to the left internus, the eye is caused to swing in excessively and too great convergence results. On the contrary, when the left eye is fixed, there is no such excess of nervous impulse sent to the left internus, and as no excessive impulse is therefore sent to the right internus, that eye swings outward passively, and crossing of images results. But in this explanation we must lose sight of the important, probably the most important, element in the causation of the inward swing in many if not in the majority of cases. This is the influence of the difference of tension of the muscles which move the eyes in the vertical direction. This influence is often sufficient, even though the moving power of the corresponding lateral muscles should be equal, to cause a swing beyond that which would result from a given impulse to a lateral muscle. I have rarely met with a case of the so-called "antipathy to single vision" in which this element did not play an important rôle.

It needs no argument to show that the defect which causes the patient to have homonymous diplopia when looking at an object, say at twenty feet distance, and heteronymous diplopia when looking at the same object, if a grating, like the fence of which we have spoken, is interposed between the eyes and the object, or which causes the same patient to have homonymous images when looking at an object surrounded by other objects, and crossed images when looking at an object isolated from visible surroundings, lies neither in the brain nor in faulty projection from the retinae, but in peculiar, although perhaps obscure, defects in the adjusting apparatus.

Homonymous diplopia caused by a brain de-

fect or a retinal defect would remain homonymous under all the circumstances which have just been mentioned. Activity or passivity of certain efforts of adjustment could and would be modified by the circumstances mentioned, and the phenomena resulting, which at first appear confused and irregular, are in reality uniform and in accordance with fixed laws.

It is not to be denied that the investigation of an individual case is often surrounded by immense difficulties, or that each new case may present new and perhaps at first incomprehensible phenomena. It is none the less true that all these cases will be found to be governed by known laws. If the difficulties of interpretation of the phenomena in individual cases are great, it demands the greater skill and patience on the part of the investigator in searching out all the various influences which combine to make the defect.

It would probably be impossible, even if all the facts were in our possession, to lay down distinct rules for the discovery of the exact nature of the faulty relations of muscular tension in each case of this class. To attempt it even to the extent to which the principle has been studied, would be to record separately the experience in each individual case. Enough has been said, however, to indicate the lines on which the investigation is to be made.

In the correction of the defect—this incompatibility to single seeing—we must logically seek to reestablish a degree of equilibrium between the mobilizing functions of the opposing muscles. To this end, after first correcting the unequal tendency in the vertical direction, it will, in most instances, be necessary to bring the insertion of the disabled muscle forward, and to reduce the tension of the corresponding one of the other eye. This procedure is by no means as easy as might appear. To readjust the tendon after such a setting back as occurs in the standard squint operation, requires in many instances the most persistent and skilful treatment.

Very little can be accomplished by a gross advancement, in which the already disabled muscle is made even less flexible than before. The object is secured by progressive steps, one slight advancement preparing the way for another, until the proper degree of rotation, with as great flexibility of the muscle as possible, is secured. Then the corresponding muscle of the other eye, if it has not been already relaxed, must be made to assume, as nearly as is required, a corresponding adjustment, by a careful relaxation.

Such a procedure has, in my hands, succeeded in establishing binocular vision in many inveterate cases of the so-called "antipathy to single vision." The process is often long and difficult, making the greatest possible demands upon the skill, courage and patience of the surgeon, and

the persistent and intelligent coöperation of the patient.

It has been my purpose to do no more than to indicate in a very general way the principle which I would advance, namely: that incompatibility to single seeing usually denotes incorrect methods of operating, and that there can be no effectual correction of strabismus which leaves the tension of the corresponding muscles of the two eyes unequal. The supposed success of many cases in which such inequality is caused by operation, doubtless results from the fact that in the remaining diplopia the images are so widely separated that the patient does not become aware of its existence.

In order to avoid the evil results of diplopia, and to secure not only possible but easy binocular vision, then, we must be guided, first, by the actual rotations of the eyes, and by the actual relations of the visual lines, not only in the lateral but in the vertical direction. This can be accomplished only when the patient recognizes the position of double pictures, and this according to the theory of identity. There should be no final operation for the adjustment of squinting eyes, until both patient and surgeon are sure of the relative position of the double images.

A precept which I have elsewhere brought forward is in this connection also of essential importance, viz.:

"Every modification of the length of a lateral muscle, by relaxation or by shortening, which can in any degree affect the rotation of one eye, should in every instance be accompanied by an exactly equivalent modification of the corresponding muscle of the other eye."

If this precept is correct, the practice of relaxing or setting back of an internus, accompanied by an advancement or shortening of the externus of the same eye, while the muscles of the other eye undergo no modification, cannot afford the best results.

The subject of the determination of the relative tensions of the various eye muscles I have already discussed at some length, in a series of articles published in the *Archives of Ophthalmology* during the years 1887, 1888 and 1889. It is unnecessary to repeat what has there been said, but there is also much more which might be said in connection with the examination of the relative tensions in these peculiar and most difficult cases, which must be reserved for another occasion.

One point, however, is so important in its relation to the subject under consideration, that it should not be separated from it. This is the examination of the comparative rotation of the two eyes in the temporal and in the nasal direction. Something can be learned from an inspection of the movements of the eyes as the surgeon causes

⁴ Anomalies of the Ocular Muscles, Arch. of Ophthalmology, 1889, p. 407.

the patient to follow with the eyes a pencil or other object as it is carried from side to side, the patient making his best efforts to see it as far toward the extreme outer field of vision at each side as possible. It will in most of the cases, in which the original operation has been performed for converging strabismus, be seen that as the eye on which the operation, or the most extensive operation, has been performed, moves toward the nasal side, its progress is arrested before the border of the cornea reaches the inner canthus.

The nasal rotation of the other eye will often be found to be free, or even excessive. But even the nasal rotation of this other eye may be restricted, only in less degree than the first. Similarly, we may observe a difference in the temporal rotation. This method of inspection, while important and in some measure satisfactory, furnishes less exact information than is required in most cases.

In the measurement of the temporal rotation, we have in the perimeter an instrument of sufficient precision. It is my custom to place in the carrier of the perimeter a few capital letters in clear type, of about the size 2 = D. of the Snellen scale, and require the patient to see the letters with sufficient clearness to read them. A glass to meet the requirements of the patient's vision is held in such a way before the eyes, that it is at a right angle to the line between the eye and the test object. Ordinarily, a pair of eyes in which no considerable degree of heterophoria exists will make the temporal rotation about 40° each, and no considerable difference in this rotation should exist. In many of the cases under discussion, the temporal rotation will be found to differ for the two eyes to the extent of from 10 to 20°. With the new model of the registering perimeter, this element can be quickly and accurately determined.

Unfortunately, we have no method so accurate for examining the nasal rotation. The full rotation of the eye in this direction in the normal condition cannot usually be determined by the perimeter, except by the supplementary use of a strong prism. Even with this supplement, the extreme rotation inward of cases of slight converging squint cannot be registered by the instrument. In cases in which the rotation does not much exceed the line of vision across the bridge of the nose, we may place a rounded prism with its apex in the canthus. Two degrees of prism equal one degree of the perimeter. Hence a prism of 10°, apex in the canthus, may cause the eye to turn inward 5° more than it would in looking directly at the object. The expedient of placing a scale of degrees on the lower lid, and reading from it the nasal rotation, while inaccurate, is sometimes the only recourse, and the best use of an unsatisfactory method must be made.

DISCUSSION.

DR. J. H. THOMPSON said that he had found the operation for squint a very difficult one to gauge. He does not now believe it is so often due to hyperopia as Donders taught, often seeing it in emmetropia. Believes it to be due in many cases to congenital amblyopia. He thinks that after a squint operation with good vision in both eyes, if there is antipathy to single vision, the trouble is in the brain. When a muscle is set back, it often does not symmetrically reattach to the globe, and a want of coördinate action leads to divergent squint. He believes in cutting very little, and in advancing the weak muscle.

DR. EDWARD JACKSON had seen three cases falling under Dr. Stevens' classes. He thought in these cases there was some anatomical defect in the nerve centres, the squint dating from infancy, and there never having been fusion of images. In one case there was anisometropia and would fix differently with the two eyes, possibly lying in a defect in the commissures.

DR. STEVENS, in closing the discussion, called attention to the want of equality in height between the two eyes, one being generally on a different level from the other. He finds this in all cases where there is no other palpable cause. On correcting this difference in level, the adjustments become more and more perfect.

HÆMORRHAGIC GLAUCOMA WITH AN ANALYSIS OF THREE CASES.

Read in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY ROBERT L. RANDOLPH, M.D.,
OF BALTIMORE, MD.

Pathologist and attending Surgeon to the Presbyterian Eye and Ear Hospital, Baltimore. Ophthalmic and Aural Surgeon to the Johns Hopkins Hospital and Dispensary. Ophthalmologist to the Baltimore and Ohio Railroad.

By hæmorrhagic glaucoma I understand that form of glaucoma which is preceded by numerous hæmorrhages in the retina, and when in the majority of cases the glaucomatous symptoms do not show themselves for many weeks after the visible retinæ changes. It is hence a secondary glaucoma. The youngest case on record occurred at 35 years of age and is reported by V. Græfe. The disease occurs most frequently in persons who have passed the fiftieth year, and there is every reason to believe that the time of life is here an essential factor. The attacks generally commence with a sensation of pricking beneath the lids, as though a foreign body were lodged there. The lachrymation is considerable and there is much conjunctival injection. The pains radiate all around the eyeball, down the side of the nose and over the head frequently back to the occiput. We have, in other words, a most aggravated form of ciliary neuralgia.

In these features the disease does not differ from acute inflammatory glaucoma, though in my opinion, the attacks last longer, and even between the paroxysms—which by the way, come on oftener toward night—the patient is rarely free from pain.

There are then no complete intermissions. Before the glaucomatous symptoms fully manifest themselves there is no appreciable increase in tension, and often at the beginning of the attack it is generally impossible to get a view of the fundus on account of the cloudiness of the media. So one cannot speak positively as regards the arterial pulse or optic nerve excavation. In the one case where I had an opportunity of making sections of the nerve no excavation was present. According to Paymstecher, these two latter symptoms are not met with in this variety of the disease.

As regards the frequency of hæmorrhagic glaucoma, fortunately the disease is of comparatively rare occurrence.

In eight years, von Graefe¹ observed in his enormous practice 22 cases. Laquer² in 268 cases of glaucoma met with about three per cent. of the hæmorrhagic variety.

As a general thing the patients affected were hypermetropic, although the disease has been known to occur in an emmetropic individual. Hæmorrhagic glaucoma, as far as I know, has never been seen in connection with myopia; arterio-sclerosis is commonly seen in this class of patients, and this no doubt explains why a not inconsiderable number die sudden deaths.

The disturbances in vision, while sudden and rapidly increasing, do not assume the typical characteristics of primary glaucoma; in other words, there is no narrowing of the visual field on the nasal side. Chromatopsia and photopsia can both be present, but as a general thing they are lacking.

The hæmorrhages which one sees do not appear to be located preferably near the blood vessels, but are to be found mostly in the vicinity of the posterior pole of the eye, the papilla and macula, in a word everywhere, over the fundus.

The hæmorrhages have generally a ragged irregular outline; seldom are they perfectly round. In addition to smaller spots of relatively lighter red, there are to be seen larger hæmorrhages of a more intense hue, which sometimes break through into the vitreous and give rise to extensive opacities of the latter. The retinal veins are tortuous and distended, just what we see in hæmorrhagic retinitis, while the arteries fail to show any increase in size.

The process can remain at this point for a considerable length of time, indeed remissions can

occur now and then, until from time to time new or more extensive hæmorrhages take place. The older hæmorrhages may undergo degeneration (fatty), and assume the white appearance seen in albumenuric retinitis, though the singular grouping of the white plaques as is seen in the latter disease is here absent.

After light perception has gone, and the glaucomatous attacks cease, there occurs not infrequently a detachment of the retina and coincident with this condition, a lowering of intra-ocular tension. Such has been the history of the first case reported in this paper. The eye tension is here below normal, and I am inclined to think that the eye will always remain just in this condition. In other cases we meet with glaucomatous degeneration of the eyeball terminating in either phthisis bulbi or in staphyloma of the cornea or of the sclera.

When one looks into the literature of his subject with reference to the value of iridectomy one meets with rather disheartening revelations. Graefe operated in six cases and with bad result in every case, and hence he advises against iridectomy. In several cases immediately after the operation there followed numerous hæmorrhages in the retina. Sometimes the operation had the effect of assuming intra-ocular tension, but the benefit was only a temporary one. Paymstecher and Horner both seemed to have practically failed to get permanent relief through iridectomy.

On the other hand Coccuis,³ Becker,⁴ and Laquer⁵, each report a case where the operation was followed by permanent benefit. General experience, though, seems to verify the fact that iridectomy is not apt to be followed by the same good results which one sees when the operation is performed for a primary form of glaucoma, and the reason of this is to be sought for in the fact that the changes in the choroid and retina are so extensive, so vital at the time that iridectomy is indicated, that the blood vessel walls cannot stand the changed condition of the circulation immediately following the operation and the effect of the latter is frequently to precipitate fresh hæmorrhage and to elevate intra-ocular tension.

Each of the three cases reported here presents the typical history of hæmorrhagic glaucoma. And in the response to the several kinds of treatment resorted to, each case brought out much that was interesting and instructive.

Case 1.—Mrs. P., 52 years old. Has for several years been subject to violent attacks of sciatica of the right leg. She has otherwise enjoyed good health, and furthermore, has never complained of her eyes. One evening before retiring she had occasion to close her right eye and im-

⁶ Annal d'ocul. lxi. p. 56.

mediately she found that everything in the room appeared as though enveloped in a cloud. She could no longer define the outlines of objects. On getting up the next morning she could not, with her left eye, recognize a person across the room. Her family physician, whom she forthwith consulted, assured her that she was suffering with an attack of indigestion and he treated her accordingly. Not getting better, she came to my office three days after she first noticed the disturbance in her vision, April 29th. R. E. V. $\odot \frac{2}{1}$ with + 1.25 D. S. L. E. V. = counts fingers in 6 ft.

The ophthalmoscope revealed numerous small hæmorrhages around the disc and in the region of the macula. Several small white plaques were to be seen near the papilla. There was no optic neuritis, though the blood vessels were dilated, and at several points not remote from the optic nerve they gave evidence of minute ruptures having occurred. Tension of the eye at this time was normal. I made a diagnosis of hæmorrhagic retinitis; a thorough physical examination was made but with negative result. The urine revealed nothing abnormal. I put her on Iod. Potas. 10 grs. three times daily, gave her smoked glasses and forbade her using her eyes. At the end of six weeks neither the objective nor the subjective symptoms had changed. About this time she went north to spend the summer, and a few days later she wrote she thought she could see somewhat better. About six weeks after she arrived she had a violent attack of sciatica and suffered intensely for many hours. No sooner had this attack subsided than she began to suffer torture with her eye. Boring, lancinating pains over that side of the face and particularly severe down the side of the nose. Her daughter wrote a most accurate account of her symptoms and I advised her to consult an oculist immediately, as I suspected glaucoma. She consulted Dr. A. Adams, of Newburgh, N. Y., and it is to his courtesy that I owe the following account of her condition. "In the afflicted eye" he writes, "I find T. + 2, pupil widely dilated and no reaction to light, slight chemosis. Ophthalmoscope showed retinal hæmorrhages, mostly old ones, but there was certainly one fresh hæmorrhage and about the size of the papilla and situated between the latter and the macula. Vitreous a little hazy. R. E. V. = $\frac{2}{0}$. L. E. V. counts fingers in 10 inches.

Dr. Adams treated her for several days with antipyrin and eserine, and she got so much better that she determined to return home. The day after reaching home she had an attack, and I was sent for. I found her suffering intensely. The tension of the eyeball was at its maximum and the media were all closed, showing the general disturbance in the nutrition of the eye. Anterior chamber shallow, and scarcely more than light perception was present.

Dry heat (in the form known as Japan Box), and eserine 2 gr.—ozj, instilled every four hours, gave her comfort for two days, when the pains returned with more violence than ever. I then determined to perform iridectomy, which latter was accomplished without accident. Relief was immediate and complete, and lasted for three weeks, after which time the pains returned, and I concluded to resort to paracentesis of the vitreous. This operation was performed with the patient sitting in her chair. I passed in a Graefe cataract knife one-fourth of its length into three points of the eyeball—above, just at the posterior and temporal side of the insertion of the superior rectus, and in the equatorial region at the nasal and temporal side. This was on the 7th of November, since which time she has been absolutely free from pain. There have been occasions when the tension has mounted up, but never a moment of suffering. The pupil is now widely dilated, and the eye is somewhat more compressible than its fellow. Light perception has gone. The retina is detached, and there are numerous striations in the lens. One rather unusual thing occurred in connection with the use of eserine in this case. A violent conjunctivitis followed its constant use several times daily, the lids became swollen and there was present the most profuse lachrymation. These symptoms, which are those of what I should call *eserine conjunctivitis*, disappeared entirely when I stopped using the drug. The disease no doubt resembles in its history what is known as atropine conjunctivitis. I have never seen any mention made in the books of this effect of eserine.

The second case is that of a woman 44 years old, who two days before labor noticed that she saw very indistinctly with her right eye. The labor was a protracted one, and when she got out of bed only light perception remained in that eye. When she consulted me, I found nothing noteworthy about the external appearance of the eye. The ophthalmoscope revealed hæmorrhages covering almost the entire fundus. Vitreous hazy.

There was hyperopic astigmatism against rule in her good eye of $\frac{1}{2}$ dioptre, and with a correcting lens she read $\frac{2}{1}$. A physical examination failed to reveal any constitutional disorder.

I told her that nothing could be done, and so put her simply on tonic treatment. Two months later she returned to me, suffering with an attack of glaucoma; the pupil dilated, conjunctiva injected, and T. + 2. I used eserine with no effect whatever. She urged me to take the eye out, but I persuaded her to allow me to perform iridectomy. The operation had the effect of relieving her of pain for a week, when the trouble returned with renewed intensity, and she insisted on having the eye enucleated. I could not induce her to allow me to perform paracentesis. I performed enucleation.

The last case is that of a man 77 years of age, who has always enjoyed fair health. The vision of his right eye suddenly began to fail him, and when he came to me, the vision in that eye was $\frac{2}{200}$. In the other eye he had a hyperopic astigmatism of 3 D., which when corrected gave him V. $\frac{2}{20}$. The diagnosis of the trouble in the right eye was hæmorrhagic retinitis. I saw the patient from time to time for six weeks, the condition of the eye remaining the same. Not long after I lost sight of him for more than a month, when he sent for me to come to him at once. I found him in great agony with his eye, which objectively presented all the symptoms of an acute attack of inflammatory glaucoma. Pupil widely dilated, chemosis of the conjunctiva, and T. + 2. I employed eserine for twenty-four hours, but with no effect. Recalling the good effects of the paracentesis in Case 1, I determined to perform the same operation here. At my next visit, the morning after the operation, the patient remarked that it was the first night's rest he had had for a week.

Relief continued for five days, when he was again attacked with the violent ciliary neuralgia. Once more I resorted to paracentesis, and with the same happy effect. Twenty-four hours later the tension of the eye had noticeably gone down, and the patient was free from pain. I continued the use of eserine three times a day, and the eye, at the end of a week, had almost regained its normal external appearance. The result of this operation was to relieve him for ten days. On the eleventh day he sent for me, and I found him suffering again. The eye was intensely congested, and the anterior chamber was filled with blood, indicating a fresh hæmorrhage. This condition determined me to enucleate the eye, as I did not think any good would follow iridectomy. The eye was therefore taken out and put in Müller's fluid, and later sections were made.

Pathological Anatomy.—Cornea intact throughout. Iris was the seat of numerous small hæmorrhages, most abundant in the neighborhood of the corneal puncture. The canal of Schlemm was not to be seen. Hyaline degeneration of blood-vessel walls. The retina showed hæmorrhages throughout its internal part, extending into the external granular layer, and only exceptionally as far as the external nuclear layer. Inner half of retina presented here and there hyaline-looking drops separated by a reticulum, and no details of this part of the retina could be made out. Between the rods and cones there were to be seen formless drops, staining deeply with eserine. In the choroid there was to be observed an absence of nuclear staining, though this was not restricted to the choroid alone, it being the case also in the retina. The veins of the choroid were enormously distended with blood, and their walls apparently showed hyaline degeneration.

In the papilla and elsewhere in the optic nerve hæmorrhages were present. The muscular coat of the central artery appeared to have undergone hyaline degeneration, as was the case with the arteries in general. Endarteritis was apparent in several of the smaller arteries.

As to the causes working to call forth the disease, in the three cases just reported we certainly have the comparative rigidity of the sclera incident upon the ages of the patients (certainly of two of them), and the refractive condition of the eyes, there being hyperopia and a certain amount of astigmatism in each case. The age of two of the patients, and the fact that they were subject to frequent attacks of sciatica and rheumatism, would lead one to look for general arterio sclerosis. In the case of the woman who went blind prior to labor, age probably played a minor rôle, but a great and permanent disturbance of the circulatory apparatus must have been associated with the protracted labor, and the walls of the ocular blood-vessels must have undergone changes different from those which are at the bottom of other retinal diseases and which we see every day, and which we know do not lead to hæmorrhagic glaucoma. The family physician told me that he had tested the urine just before labor, and found a considerable quantity of albumen present. Another cause common to all three cases, and which is especially potent in the production of the disease, was the ciliary irritation, a condition tending to increase the fluid contents of the eye, according to experiments made on animals by von Hippel and Gründhagen.

With such numerous hæmorrhages and such widespread disease, the changes in the blood-vessel walls and in the substance of the retina itself must be of the highest grade, and consequently we would look for increased transudation and lessened resorption. It is impossible, of course, to predict anything as regards the continued soundness of the other eye in each case. Von Graefe reports the fact that of twenty-two cases, in ten the other eye had remained perfectly intact, although in this respect the disease can show the greatest variations. In four cases Graefe observed five months later the approach of hæmorrhages in the other eye, though glaucoma was absent. In one case, soon after the disease showed itself in the first eye, an intense retinal hyperæsthesia occurred in the other eye, characterized by seeing sparks and flashes of light. This disappeared. In six cases the second eye was finally attacked and blindness followed. Nearly a year has passed in the first of my cases, ten months in the second and seven months in the last case, and in each instance the other eye retains normal vision. As I said before, it was a matter of regret to me afterward that it was not possible in the second case to perform paracentesis. The patient would consent to no more attempts to

save the eyeball, and if I had the third case to treat over again, I should certainly try iridectomy first, and if necessary follow it up by paracentesis of the vitreous in the manner described above. There is no telling what the combined effect of these two operations might have brought about. They certainly realized every hope in the first case. And though permanent and positive relief was seen in only one case, one will gather from reading the history of the cases, that the whole tendency of the operations of paracentesis and iridectomy was to improve the condition of the patient, and hence I should conclude that iridectomy is not contraindicated in this form of glaucoma, but on the contrary, the operation does give temporary, and may give lasting, relief from suffering, and consequently it should always be tried first; and finally, that in paracentesis in the manner described in Case 1, it is possible still further to ameliorate the condition of the patient. As to prophylaxis in its bearing upon the other eye in each of these cases, I think this simply means sparing the eye all work, and absolute freedom on the part of the patient from mental and bodily fatigue.

And though the results of treatment in these three cases were far from brilliant, it is just in these kinds of extreme eye troubles, which have generally unsuccessful issues, that the histories, when carefully told, benefit us quite as much as brilliant results.

DISCUSSION.

DR. DE SCHWEINITZ reported cases of hæmorrhagic glaucoma with numerous small hæmorrhages, with cupping in one eye and no cupping in the other, due to arterial sclerosis. In the second case, only one eye being affected, there were widespread hæmorrhages obliterating the macula. There was albuminuria, a history of syphilis, and doubtless atheroma of the arteries.

DR. AYRES said iridectomy had been very unsatisfactory in hæmorrhagic glaucoma. He favors enucleation if no other means brought relief.

DR. J. H. THOMPSON does not favor enucleation, but prefers, instead, optico-ciliary neurotomy.

DR. RANDOLPH answered Dr. Thompson that he had seen many failures from optico-ciliary neurotomy in Baltimore, and did not approve it.

BOOK REVIEWS.

ATLAS OF CLINICAL MEDICINE. By BYROM BRAMWELL, M.D., etc., assistant physician to the Edinburgh Royal Infirmary, etc. Volume I, Part 1. Edinburgh: T. and A. Constable. 1891.

The first part of the first volume of this work has just been issued, and treats of Myxœdema; the clinical investigation of cases of Myxœdema; Sporadic Cretinism; the clinical investigation of sporadic cretinism; Myxœ-

dema and Exophthalmic Goitre contrasted; Friedreich's Ataxia; the clinical investigation of Friedreich's Ataxia; notes of three additional cases of Friedreich's Ataxia.

The text is illustrated by five well executed plates, viz: 1, 2, 3. Myxœdema; 4, 5. Sporadic Cretinism.

With this part are also issued two additional plates, the first illustrating Lymphadenoma, and the second, Melancholia with Fear.

It is designed to issue the work in four parts each year, very fully illustrated. If that portion already issued is to be taken as a fair specimen of what is to follow, it may well be regarded as a work of more than ordinary merit. The first yearly volume is to contain thirty plates, 14½ by 10½ inches, colored, black and white, and photogravure, with detailed description of the plates and text. The Atlas will be issued to yearly subscribers only, and it is contemplated to continue the work through three years, and to include at least ninety illustrative plates.

ESSENTIALS OF SURGERY, together with a *Full Description of the Handkerchief and Roller Bandage*. Arranged in the form of questions and answers, prepared especially for students of medicine. By EDWARD MARTIN, A.M., M.D., Instructor in Operative Surgery, University of Pennsylvania, etc. Illustrated, fourth edition, revised and enlarged by an appendix, containing full directions and prescriptions for the preparation of the various materials used in antiseptic surgery, etc. Philadelphia: W. B. Saunders. 1891.

The first edition of this number of Saunders' Question-Compends appeared in 1888, and has now reached a fourth edition. Whatever view may be held as to the value of such aids to students it is evident that there is a demand for them, and this is no doubt increased by physicians who find such compends a convenient mode of reviewing the subject of which each treats, and which is supposed to be brought abreast of the times on that particular subject, so that he may get in a convenient way and in a concise form some of the most recent ideas on the subject, without sifting from the general literature of the subject.

The present number is one of the best of the series. The author may be said to have accomplished his avowed purpose of having furnished the "essential points as a framework upon which more detailed knowledge may be hung." His further claim "to be accurate, concise and modern" is well founded. The additions made in the present edition are noted on the title page.

SYLLABUS OF THE OBSTETRICAL LECTURES in the Medical Department of the University of Pennsylvania. By RICHARD C. NORRIS, A.M., M.D., Demonstrator of Obstetrics in the University of Pennsylvania, etc. Second Edition. Philadelphia: W. B. Saunders. 1891.

The first edition of this Syllabus was issued in 1889. This second edition has some additions, including chapters on infant feeding, pathology of the puerperium, obstetric operations and dystocia.

In addition to the table of contents, an index has been added, and it is interleaved for convenience in note taking. Being largely based on the course of lectures delivered in that University, it doubtless proves a great convenience to the students of that institution to whom it is dedicated, and no doubt will be so, in perhaps a less degree, to students in other institutions. The author may be congratulated on having been more than ordinarily successful in the task which he undertook in preparing the syllabus.

THE CONSTRUCTION OF SCHOOL BUILDINGS.

Read in the Section on State Medicine at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY D. F. LINCOLN, M.D.,

OF GENEVA, N. Y.

CHAIRMAN OF THE COMMITTEE ON SCHOOL HYGIENE OF THE AMERICAN MEDICAL ASSOCIATION.

In dealing with this question, we are obliged to make allowance for difference in circumstances. We demand space, fresh air, light; and these needful things undeniably cost money. The poorer and less enlightened communities will grudge payment, even for such necessities of life; but the number must be very small, of those who have not a disposition to improve, and a willingness to make some sacrifice. The burden does not always fall heaviest upon the poor districts; land costs next to nothing in the country, and the struggle for elbow-room between tall overshadowing buildings is unknown, while in rich cities it may happen that the millions appropriated for public schools are as inadequate as the hundreds granted by a country district.

The city school is greatly restricted in the space available for building; and in no city is this difficulty more pressing than in New York. Without assuming the right to condemn any one's omissions, we may still be permitted to offer suggestions which may meet with appreciation in certain quarters.

The suggestion, then, which is first offered, is to this effect, that it would be well if the space surrounding each school-house could be at the outset ample for the purpose of supplying light, and that regulations might be made to prevent encroachments upon the sky area. It could be ordered, for instance, that the width of such space be made equal to the height of buildings now standing, or likely to be erected, in contiguity; and that the height of such future adjoining edifices should be restricted. It may be difficult to anticipate the future. But surely we need not commit the blunder of allowing only a six or ten foot passage at the side of the school-house—of which it would be easy to point out examples.

To the recommendation of a liberal ground space may be added another of kindred character: that of moderate size and height in the edifice. The reasons for this are various. On the one hand, there are objections to the massing of great numbers of children; there is the difficulty of management to be considered, and other matters, the discussion of which may be omitted here. Apart from this, there are objections to the great, compact house, the central parts of which are remote from the freshness of the outer air and the beneficial effect of sunlight. Then there is the objection to many-storied buildings, on the ground of loss of time in passing scholars to and from the yards at recess, and on the further

ground of occasional injury to the system in the case of girls in their teens, at the period of sexual development.

The safety of the inmates in case of fire should be insured by suitable arrangements of stairs, and by strict drill. I cannot approve of the ladders or twisting stairs of iron openwork clamped to the outside of the building, as a refuge for a crowd of panic stricken children. Safety requires that the ordinary staircases be planned so as to be incombustible, and that they should present no impediment or trap for the foot, such as spiral curves, narrow-cornered steps, steepness or dark passages. Stairways ought to be so placed that every room has access to more than one, in different directions.

Lighting.—The best opinions at present, in this country, seem to agree in preferring light which enters from the left side of the pupils, and in absolutely objecting to that which enters in front. Whether light should be admitted from the right hand or the rear cannot be categorically stated; in some circumstances (as in the case of small country school-houses), it seems a desirable addition to the left-hand light.

There are two mistakes, against which serious warning should be given. One is the placing of windows at a low point, for architectural or other æsthetic reasons. The best place for the light to enter the room is the highest point attainable. Windows should nearly touch the ceiling, and their upper part should be as free as possible from incumbrances which obstruct light. The other mistake referred to is the attempt to light very wide rooms of moderate height by side windows. The poverty of light in such cases is not to be estimated by the ordinary standards, or by one's impressions, but by observing the way in which the horizontal rays of light fall on a book placed flat on the desk as for study.

Verandas are fatal to good working light. The "Italian" awning is nearly as bad. In general, no form of curtain or other screen covering the upper part of a window is allowable except on the ground of strict necessity. If shades are required to exclude the sun, they must be removable when not needed.

The eye should be favored by avoiding the glaring effect of pure white walls; a slight neutral tint, or bluish or greenish, is preferable. The ceiling, however, may be as white as possible.

School-rooms.—Their dimensions are partly dependent on the requirements of ventilation. It may be added, that their length is limited by the distance at which the ordinary eye can read ordinary work on the blackboard, or not greatly over 30 feet. The width should not exceed the moderate dimensions which are compatible with good lighting—from 22 to 25 feet if light comes from one side.

The floors should everywhere be made of material which can be washed conveniently—a wood which will not splinter or wear ragged.

Seats and desks.—The American patterns in common use are at least comfortable—from one point of view. The chairs are very easy to sit back in when one is tired. In this they differ widely from the accepted patterns of the European schools, whose children are taught to sit up straight, and are furnished with short backed seats which support the hips sufficiently, but not the shoulders. These models are strange, to our eyes, and there is little chance of our rocking-chair-loving race adopting them at present. They possess obvious merit, however.

From the Germans we have learned that the front edge of the desk must reach or overhang the edge of the seat. This principle is commonly imitated among us. What we have not yet seen fit to adopt is the no less rational principle that the desk should not crowd the arms and elbows upward. The arms ought to hang so freely that the elbows, when writing is going on, are at the level of the desk. In no other way can we insure a correct—*i.e.* a straight and squared—position in writing.

In conclusion, let me say that a number of points have been left untouched in this paper, which might properly have been treated of, as related to the general subject of construction. This is due to the fact that a special assignment of the subject of drainage and sewage has been made, by which it is placed in the hands of another member of the committee; his work is expected at the next annual meeting.

PRE-COLUMBIAN SYPHILIS.—The growing prospect of a world's fair in 1892 or 1893 arouses an especial interest in things Columbian and pre-Columbian. Possibly among the latter may be classed syphilis. Dr. James Nevins Hyde discusses the question in the *American Journal of Medical Sciences*, and the discussion will, we trust, be continued. America has heretofore accepted too readily the dubious compliment of having bestowed upon civilization the *grosse vérole*. When one recalls what a sty of licentiousness and filth Europe was in the fifteenth century, it seems much easier to suppose that syphilis was bred there than that it was imported. Dr. Hyde, however, takes up mainly the question whether the North American Indians of pre-Columbian times left any bones which show evident syphilitic lesions. A good many so called pre-historic bones showing signs of so called syphilis have been collected. But it has been shown that many of the remains in the Indian's mounds and caves are not pre-historic. Then, so far as the lesions are concerned, it appears to us from the evidence presented that none of them are plainly the results of syphilis.

Dr. Hyde reports in detail the results of a microscopical study of two tibiae from Colorado, made by Dr. T. M. Prudden. These showed the presence of a chronic rarefying and formative osteitis and chronic formative periostitis, changes which might be of syphilitic origin, but much more likely were not.

So far as the bones have yet told the story there was no pre-Columbian syphilis.

Its presence will have to be established by further bony studies, as well as by historical, and perhaps philological investigations.—*N. Y. Med. Record.*

MEDICAL PRACTICE IN CONNECTICUT.—The *Monthly Bulletin of the Connecticut Board of Health* contains the following reply, sent to a doctor inquiring of a State official if he would be allowed to practice in Connecticut by registering his name and the college from which he graduated: "SIR:—Anybody can practice medicine in Connecticut. You do not need to register; you do not need a medical diploma; you do not need to know the difference between opium and peppermint—you do not, indeed, need to know anything. You can simply come and live here, and begin to practice. The laws of Connecticut will sustain you in collecting your fees for professional services, if you render any which you choose to call such. But if you undertake to carry me or my trunk to the depot for pay, you must get a license. If you peddle matches or peanuts, you must get a license. If you collect the swill from your neighbors, to feed your pigs, you must get a license. If you want to empty your cesspool, you must get a license. But you can practice medicine in Connecticut *without a license*."—*Boston Med. and Surg. Journal.*

LEPROSY IN JAMAICA.—Dr. Donovan, in his annual report to the Governor, on the Lepers' Home, Jamaica, estimates the leper population of the island at 450, or one leper to 1,380 of the population. Pending general legislation on the question of isolation, he recommends a prohibitive enactment against lepers keeping provision stores or being employed therein, or in the preparation of food; that no leper be allowed to engage in any of the following vocations, namely: baker, butcher, fisherman, tailor, school-teacher, etc.

FOR PERSISTENT DANDRUFF.—Dr. Stephen recommends that we should use a mixture of 3 scruples each of resorcin, olive oil and sulphuric ether, and 6½ ozs. of alcohol. To be well shaken and applied to the scalp by a bristle brush about twice as large as the ordinary mucilage brush, by insinuating it with the locks of hair; the head to be well washed with soap and warm water twice a week.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WARASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, SEPTEMBER 12, 1891.

TREATMENT OF CROUPOUS PNEUMONIA.

A review made a few years ago of the cases of pneumonia treated at the Massachusetts General Hospital showed that there was little or no difference in the mortality under various methods of treatment; that whether heroic onslaughts were made on the disease by the so-called antiphlogistic plan, blood-letting, and active purgation, or whether a purely expectant plan of treatment was pursued, or supporting efforts by stimulation were employed, the percentage of mortality was not materially different. Nevertheless, but few practitioners are ready to admit that their efforts in this disease are without avail, although many will be ready to admit that the results of treatment are sufficiently unsatisfactory to warrant careful attention being given to any plan which offers a rational procedure, no matter how widely it may differ from the methods now generally in vogue.

All authorities are agreed that the danger point in pneumonia is the heart, but all are certainly not agreed as to the mechanism of this danger.

We are all too prone to regard the *left heart* as the heart, and to forget that there are two hearts, more or less independent of each other. Dr. S. HENRY DESSAU, in the last number of the *Archives of Pediatrics*, reviews the subject quite

fully, referring to the work of Dr. A. H. SMITH, of New York, in a paper read before the Berlin Medical Congress in 1890. Dr. SMITH called attention to the interference with the circulation produced by the engorgement of the lung, and showed that the *right heart*, and not the heart as a whole, was the main source of exhaustion, and that the character of the second pulmonary sound was a better guide to the conditions present than the pulse. The pulmonary circulation is obstructed by the permanent dilatation of the vessels in the engorged lung, and overcrowding of the right heart necessarily occurs. In the systemic circulation, on the other hand, the arterioles are contracted, forcing the left heart to more rapid and more powerful contractions, which result in overfilling the veins, and forcing upon the already overburdened right heart a surplus of blood to be handled. The overcrowding of the right heart from the venous side tends to produce dilatation of the right ventricle before a compensatory hypertrophy can be established. It is not surprising, therefore, that in individuals in whom the nutrition of the heart muscle has been seriously impaired, as in alcoholic or nephritic cases, the mortality from pneumonia should be unusually high.

With this view of the pathology, the treatment, so far as the circulation is concerned, consists in relieving the right heart by increasing the capacity of the systemic arterial system, and by diminishing the pulse rate.

As a means of dilating the cutaneous blood vessels and producing diaphoresis, DESSAU suggests spirits of nitrous ether, DOVER's powder, or spirits of mindererus. The warm bath at 95° F., or sponging of the entire body with water at 116° F. is also recommended. The warm bath and hot sponging are given for the purpose of dilating the cutaneous vessels and inducing diaphoresis, and should be so conducted as to accomplish these ends. Conjointly with these means, the use of friction to the skin may be advantageously employed.

As a further means of relieving the right heart, efforts should be made to divert the venous blood into the liver, a reservoir capable of holding a great quantity of this fluid. It is also suggested that the increase in blood to the liver will stimulate its functions, among which is to be noted the destruction of poisonous principles in the blood.

For the purpose of stimulating the liver, he suggests the use of small doses of calomel.

Aconite is mentioned as a remedy which, carefully administered, will reduce the heart's action without depression, and furthermore assist in dilating the cutaneous vessels and promoting perspiration.

With regard to digitalis, it is urged that it can only do harm, by contracting the arterioles of the systemic circulation and increasing the force of the heart's action.

The use of aconite and veratrum in pneumonia has long found favor in the hands of many practitioners, who were unable to reconcile their good results with the objections of the theoretical men who insisted that aconite produced slow collapse.

The favorable action of calomel in pneumonia has been often noted by many practitioners, particularly those of the older school, but it seems reasonable to suppose that, with such indications for its use as are given by DR. DESSAU, better results may be expected than could be obtained by a merely empirical exhibition of the remedy.

While seeking measures to relieve the heart of the strains thrown upon it, it should not be forgotten that there are other features to be considered in pneumonia. The disease is accompanied with various nervous manifestations, evidences of the poison at work, which cannot be accounted for simply by the elevation of temperature. These poisons must be directly counteracted or eliminated. Fortunately, the means employed to relieve the right heart also assist in elimination, and in this way are probably doubly useful. But the necessity of using the most appropriate channel of elimination in the particular case must not be overlooked. In some instances, particularly in those in which typhoid symptoms, coma, and low muttering delirium intervene, with low temperature, the modern antipyretics, judiciously used, appear to exercise a truly antidotal specific effect.

How far DR. DESSAU's views may be found to stand the critical examination of the future, they are certainly at present worthy of careful consideration.

THE UNIVERSITY OF VERMONT.—DR. CONDIET W. CUTLER, of New York, has been appointed Professor of Skin and Venereal Diseases, to succeed Dr. R. W. Taylor, who has resigned.

IMMUNITY AGAINST CROUPOUS PNEUMONIA.

While upon the subject of the treatment of pneumonia, the experiments of Prof. EMMERICH of Munich, relating to the production of an artificial immunity against this disease and to curing the same, should be noticed. EMMERICH has just reported his experiments before the late Congress of Hygiene and Demography in London.

From previous experiments EMMERICH has been led to believe that immunity against infectious disease is produced by a toxine inimical to bacteria, but innocuous toward the cells of the animal body. In an immune animal, at least soon after immunity has been produced, this substance should be found in its blood and other tissue fluids.

By subjecting a rabbit to an intravenous injection of a very dilute but completely virulent culture of the *diplococcus pneumoniae Fränkelii* it is rendered immune. Rabbits so prepared were killed, skinned, divided and rubbed up into a fine paste, which was pressed through the meshes of a clean sterilized cloth. The bloody juice was kept for twelve hours at a temperature of 10 C. (53.8° F.) then sterilized by passing through a Pasteur filter. Twenty-six rabbits, one of which had been subjected to an injection of the immunizing juice, were subjected in an inhalation apparatus to the action of a spray of bouillon culture of diplococci. All died speedily except the one animal protected by the immunizing juice.

In a second series of experiments seven mice were injected with a virulent culture of the *diplococcus pneumoniae*, in quantities varying from 3 c.c. to 5 c.c. Six of them were then injected with the immunizing or curative juice as it may now be called. In 44 hours the unprotected mouse was dead, the autopsy showing diplococci in the blood and internal organs in great quantities, while the other six mice were all well. As these last experiments were made during the last three days of July, we must wait further for fuller returns.¹

In a further experiment with three mice, the first two were injected with .5 c.c. and the third with .3 c.c. of a virulent culture. Five hours later the first two mice received 2 c.c. of the curative juice, but not of a fresh preparation.

¹ Maximilian Herzog, Cincinnati Lancet-Clinic, Vol. xxvii, N. S. 301.

The following day all of the mice were sick, the third being worse than the first two. The first was given an injection of 1 c.c. of perfectly fresh curative juice, whereupon it recovered rapidly. The second and third both died.

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Washington, September 22, 23, 24. The apparent indications are that this will be a great success, both in attendance and in the character of the papers, with accompanying discussions. The coming together of leading investigators and specialty practitioners in the various departments of our art will be fraught with great good especially to those who attend the Congress, as well as to the profession at large.

The men who have won renown by reason of their attainments, are usually the ones who are most wide awake and ready to pick up and utilize the expressed thoughts of their fellows, while very often their own idols are shattered beyond possible recognition.

Specialists in the great Eastern, Central, Western and Southern cities will do well to place themselves in more close affiliation with each other. Art and science are cosmopolitan. The assemblage of men engaged in similar lines of labor and thought, from every geographical direction, favors the dissemination of knowledge, besides placing themselves one with another in desirable business channels.

The social features of these gatherings of the intellectual laborers in our particular vineyard are hardly, if at all, second to the ostensible purpose of the occasion.

The men who can go, ought to do so as a matter of duty owed to themselves, as well as the more unselfish one they owe to others. It is quite doubtful if any professional workingman's annual income appreciably suffers through his attendance at medical society meetings.

The world has come to not only regard and recognize, but to know that organized labor, is more skillful, more effectual and more complete in its performance of a given work than that which is done under conditions of segregation.

Joined and welded together for a common purpose, a great profession like that of medicine is capable of doing an unlimited amount of good

both for its individual members and for the people at large. No man can alone accomplish and work out of his own ideals, he must have the aid of his fellows. This may be had at a society meeting.

THE "CATHOLEPISTEMIAD OR UNIVERSITY MICHIGANIA."

Have we a "Catholepistemiad" in our midst? A curious bit of the educational history of the territory of Michigan—inclusive of a medical embryo—has been brought to light in Dr. F. W. BLACKMAR'S essay on "State Aid to Higher Education in the United States." Dr. BLACKMAR is a member of the faculty of the University of Kansas, and his essay is one of the circulars of the Bureau of Education. The following paragraph shows that medicine was one of the projected departments of an institution of learning, based on a broad foundation, as far back as 1817, when the population of the territory did not number over seven thousand souls. The grant of a township of land for a seminary of learning was made by Congress as early as 1804, but the enabling act for the establishment of a university did not pass the territorial legislature until 1817. In that year, "the territorial government committed the interests of higher education to the care of the governor and the judges, and it is supposed that through the exertions of Hon. A. B. WOODWARD, then presiding judge of the supreme court of the Territory of Michigan, that the act establishing a university was framed. A portion of this most curious document of the early history of Michigan will be given. It is entitled An act to establish the Catholepistemiad or University Michigania.

Be it enacted by the Governor and Judges of the Territory of Michigan, That there shall be in the said Territory a catholepistemiad or university denominated the Catholepistemiad or University Michigania.

The Catholepistemiad or University of Michigania shall be composed of thirteen didaxum or professorships; first, a didaxia or professorship catholepistemia, or universal science, the dictator or professor of which shall be president of the institution; second, a didaxia or professorship of anthropoglossica, or literature embracing all of the epistemonum or sciences relative to language; third, a didaxia or professorship of mathematica

or mathematics; fourth, a didaxia or professorship of physiognostica or natural history, etc. The act thus continues through the whole range of the thirteen didaxum. The remaining nine are as follows: Natural philosophy, astronomy, chemistry, medical sciences, economical sciences, ethical sciences, military sciences, historical sciences, and intellectual. The university was to be under the control of the professors and president, who were to be appointed by the governor, while the institution was to be the center and controlling power of the educational system of the State. It was to be supported by taxation by an increase of the amount of taxes already levied by 15 per cent. Also power was given to raise money for the support of the university by means of lotteries.

This remarkable document was not without its influence in shaping the public school policy of Michigan, but it was many years before the State approximated its learned provisions. Impracticable as this educational plan appears for a handful of people in the woods of Michigan, it served as a foundation upon which to build. The officers and president were duly appointed, and the work of the new university began at once."

Although the teaching of medicine was thus early taken into consideration by the founders of a great State, thirty years elapsed before the first medical faculty of Michigan took on its outward form and feature.

ONE THOUSAND CASES OF PNEUMONIA TREATED IN HOSPITAL.

DR. FENWICK, of the London Hospital, has given to the *Lancet* an analysis of 1,000 cases of pneumonia seen in that institution during the last ten years. Cases admitted shortly before death took place or twenty-four hours before a critical turn in the disease, are omitted from this report. In the sthenic cases, which numbered 500, the treatment was generally along the three general courses described as follows:

First. Treatment by means of hot applications to the chest, in conjunction with remedies having tonic and expectorant properties. The mortality in this class of cases exceeded 20 per cent. Second. Cases in which the only treatment was by quinine in large doses. The mortality here exceeded 20 per cent. Third. Cases

where the treatment was by various antipyretic measures. In twenty-six of these, cold applications to the chest were employed, with a mortality of 15 per cent. The cold pack was tried in an equal number of cases, with about the same mortality. Cold sponging, used in fifty-six cases, had a mortality of 13 per cent. The "ice cradle" was used in forty-three cases, mortality only 7 per cent. By all the various cold applications 108 cases were treated, with 10 per cent. of failure. By all other grouped phases of treatment, the losses were double those by the cold method. Stimulants were given in these latter cases whenever indicated. Cold appears to be the best of the antipyretics for the class of patients with which DR. FENWICK has to deal, chiefly for the reason that it has less of depressant action upon the heart than antipyrin, quinine, etc. In the earlier stages of the disease, the true treatment involves a reduction of the temperature without cardiac depression. In the later stages, the pulse is the great guide for treatment in the matter of strengthening the recuperative forces by means of stimulants. In many cases, camphor, digitalis and alcohol will not be needed, but in impending cardiac failure these agents become vastly important. The period of crisis, also, is attended with especial dangers referable to cardiac incapacity, and it is necessary to be watchful and guard the patient, at this stage, by means of alcoholic and other suitable forms of stimulation.

A NEW DISEASE.

A disease popularly designated in the south of France under the name of "maladie des cannes de Provence," or in other words, the cane-disease, has recently been described by DR. VINCENTE GOMEZ in the *Revista de medicina y cirugía prácticas*. He reports three cases of occupational disease, apparently due to the reeds. His first case was that of a man of 50 years, who had worked with the reeds for ten years. The canes lately used had been collected during the previous winter, and were covered with a fine ash-like dust, which was diffused through the air as the canes were moved. On the day following the first active diffusion of this dust, the man was taken with an intense headache, loss of appetite, insomnia; perspiration became profuse and urine scanty. A painful tumefaction of the nasal and

buccal mucous membrane followed, with epistaxis. There was also some irritation of the external genitals. On the sixth day, there was some low febrile action, a slight amount of albuminuria, anorexia, with dry tongue and fetid breath, dull red, scaly eruption on the cheeks; prepuce inflamed and very painful, with complete phimosis. In the two other cases the attack was less marked, for the workmen, seeing the dust arising in a cloud when the canes were agitated, and knowing something of its irritating properties, quit their work. This dust is most abundant upon those canes that are cut on marshy ground after exposure to both heat and humidity. The gravity of the morbid influence of this dust seems to be in proportion to the amount of it that is present and diffused through the atmosphere wherein the cane-workers are employed, and as remarked above, those who have had experience with this *maladie des cannes* find it expedient to escape from the dust when a large package of their working material is opened or agitated. DR. GOMEZ attributes the affection to products of fermentation (zymosis), which develop upon the reeds. A microscopical examination has not yet been reported.

REFRIGERANT LANOLINE UNGUENTS.

Professor UNNA gives in the *Therapeutische Monatshafte* the results of numerous experiments with lanoline and ointments made therefrom. Among the earlier researches of himself and others it was thought advantageous to mix water with lanoline in order to get a good base for a variety of cooling unguents, this being done for the reason that very considerable quantities of water—or aqueous solutions—could be incorporated with lanoline, and it came to be thought that these mixtures would have refrigerant properties in consequence of the continuous evaporation of their contained water, by the heat of the surface of the body. But the results did not at all confirm the hypothesis, for even if such lanoline and water ointments did appear at first to be cooling, this sensation disappeared quite rapidly and was followed by a sensation of heat. UNNA then discovered that an admixture of lanoline with fats will take up large quantities of aqueous solutions, and yield combinations that are continuously and in a high degree cooling. Hence, according to

UNNA's explanation, it is to be assumed that the anhydrous lanoline holds the water too closely, so that evaporation cannot occur with sufficient rapidity, but by mixing fat or oil with it the compound is rendered less tenacious of water, and therefore the desired degree of evaporation can quite readily take place. UNNA reckons that the best proportion of lanoline: of glycerine fats: and of aqueous solutions is as 10.0: 20.0: 30.0, for the compounding of a cooling ointment; while if he has in view a cooling cream (cremor) the proportion should be 10.0: 20.0: 60.0. A simple refrigerant ointment, to be used as a cold cream, may be made as follows:

Anhydrous lanoline	10.0
Benzoated lard	20.0
Rose water	30.0

The following is a lanoline imitation of GOU-LARD'S cerate:

Anhydrous lanoline	10.0
Benzoated lard	20.0
Solution of subacetate of lead	30.0

A lanoline salve for burns is the following:

Anhydrous lanoline	10.0
Benzoated lard	20.0
Lime water	30.0

A refrigerant zinc ointment:

Anhydrous lanoline	10.0
Benzoated zinc ointment	20.0
Rose water	30.0

UNNA advised that, in this form of cooling unguents, only the anhydrous lanoline (lanolinum anhydricum) should be prescribed. These formulæ are designed for extemporaneous use, and are unsuitable for storing.

POISONING BY SULPHONAL.

A writer in the *Medical Press and Circular* gives a caution regarding the very indiscriminate use to which sulphonal is frequently put even by the laity. This drug was introduced about three years ago as a perfectly safe soporific, and corroborative testimony of this hopeful candidate have been abundant. Latterly there have been a few contrary reports about the safety and efficacy of the remedy, and the size of the maximum or poisonous dose could not be unanimously agreed upon. We have not a few cases on record where about three tablespoonfuls have been taken to produce sleep; in one of these cases the sleeper slept the greater part of five days and a half with-

out permanent injury to his nervous system. Another person took a dose about one-third smaller, but never reawakened. A more unusual and extreme case has recently been reported by DR. ERNEST NEISSER. A chemist's assistant, aged fifteen years, took with suicidal intent the contents of two boxes containing fifty grammes each, equivalent in all to three ounces, and over, of the fine pulverized sulphonal. The greater part of the drug was taken mixed with water, but some part of it was swallowed dry, and all of it was ingested within forty-five minutes. Six hours later he was found lying in a comatose sleep and was sent to a hospital, where he lay five days and nights in an unconscious condition. On the sixth day the awakening process took place gradually and on the ninth day he was discharged cured; he was apparently perfectly recovered from all the after-effects of the enormous doses he had taken. In the great disparity of these recorded cases, we read the lesson either of a want of uniformity in the manufacture of the drug, or of an undiscovered "personal equation" in those cases where the comparatively small dosage resulted fatally. At all events, a certain amount of caution should be observed when ordering the drug for patients who have not heretofore been brought under its influence.

SILVER CHLORIDE IN WHOOPING-COUGH.—Lœffler advises the use of freshly prepared chloride of silver in the prevention and treatment of whooping-cough. As given in the *Boston Medical and Surgical Journal*, his preferred combination is the following: Chloride of silver (freshly prepared), $1\frac{1}{2}$ grains; water, 2 pints; hyposulphite of sodium, a saturated solution. Mix. Use by an atomizer, the spray being directed into the pharynx. Repeat the application every two or three hours.

AT THIS season of the year the conditions of travel are as nearly perfect as possible, and for those going from south and west points, a railway ride over the mountains, by way of the Chesapeake and Ohio route, is a luxury that is charming beyond description, while the car service is as perfect as one may expect to find on wheels. The delegates who attended the late meeting of the American Medical Association and went over

this route, were profuse in their expressions of pleasure and appreciation. Wisely, the Arlington Hotel has been made the professional headquarters of the Congress of Physicians and Surgeons. The accommodations of this hostelry are ample, and in every respect equal to the demands of the most fastidious. Those who go and want to be in the swim should engage rooms at the Arlington.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

For a time during the month of August just past, the temperature was higher than for many years previously in this city; yet, strange to say, the fatal results due directly to the heat were proportionally very small. The total number of deaths directly attributable to the heat was 48, and of these, 37 occurred during the three hottest days, August 10, 11 and 12; when the highest point registered by the thermometer was respectively 98, 95 and 92 degrees in the shade, and 135, 134, and 133 in the sun. The statistics of the Health Department fail to show any such register since 1866, when the complete records begin. These records show that the heated term in July, 1872, was the most fatal that the city has experienced. During this famous hot week which ended on the sixth of July, the mortality rose from 807 (that of the previous week) to 1,591. The following extract in regard to this week is taken from the books of the Health Department:

"Although an excessive mortality for the summer, as compared with the rest of the year, is periodical in New York, the unwonted period of its occurrence in 1872 was peculiarly striking. The maximum mortality of the year had never previously been recorded so early in the season. It will suffice to go back as far as 1855 in corroboration of this fact. From that time during ten successive years, the greatest weekly number of deaths was never attained until the third week in July; in one year (1857) it was delayed until September, and in six out of the ten until August."

The highest temperature reached on June 30, July 1, 2, 3 and 4, in 1872, was 95, 95, 96, 94, and 95, respectively, in the shade, and 124, 125, 128, 120 and 123 in the sun; while the mortality from sunstrokes on these days was respectively 7, 34, 68, 43 and 44. These figures show that, in spite of the fact that the temperature was markedly higher in the hot spell in August of this year, the mortality of that in July, 1872, was markedly greater than has been the case in the latter. A possible explanation of that fact may be found in the circumstance that, whereas in 1872, the extreme heat came suddenly at the beginning of the season, thus finding the population totally unprepared for the severe strain, this year the trying time very late in the season, after several weeks of warm weather, which gave the people a chance to be prepared for it.

Since 1872, there has been no year in which the number of deaths from sunstroke has approached its large total of 320, although six years before that, in the summer of 1866, the number nearly equalled that, viz.: 310. Only three times within the past seventy years has the mercury in this city reached or exceeded the 100 mark. In July, 1821, the temperature reached 100 degrees in the shade, and in July, 1825, it reached its highest known record of 107. There are, however, no statistics preserved of the mortality of either of those months. The third time was in September, 1881, when the mercury registered 101.

It seemed appropriate that during the hot weather of August, the first permanent public baths ever established in New York should be opened to the public. The free baths along the two river fronts of the city are, of course, an inestimable boon to the poor; but in them the water is not always as clean as could be desired, and, from the nature of things, they can be enjoyed only during a comparatively limited portion of the year. The "People's Baths," which have now been inaugurated, not by the city, but by the Association for Improving the Condition of the Poor, it is proposed to keep open for fifteen hours a day during every day of the year. The system adopted is that of the rain or shower bath now in successful use in Vienna and other European cities, and it was principally due to the advice of Dr. Simon Baruch, who is such a high authority on balneology and hydro-therapeutics, that this plan was followed in the construction of the baths. Early last spring he read a paper before the Section of Hygiene of the New York Academy of Medicine, in which he urged the superior cleanliness and economy of the rain bath system for general use, and made a forcible plea for the establishment of permanent public baths of this character in New York.

The matter was at once taken up by the Association for Improving the Condition of the Poor, a society which for many years has been doing a vast amount of good by systematic and intelligent charitable work. To quote the language of the President, in his address on the occasion of the formal opening of the baths, "this Association is not merely a relief society, but it has ever in view the amelioration of the conditions, often unhealthy and uncomfortable, under which so large a proportion of the inhabitants of the city are compelled to live. It strives to better these conditions through its sanitary department, which is in constant communication with the Board of Health, receiving from the latter the most effective advice and coöperation. It also carries on a great work in sending 1,500 to 2,000 people, chiefly mothers and children, weekly to its establishment on Coney Island, where they have fresh air, abundant food, sea bathing, and much innocent enjoyment."

Some time ago the New York City Mission had received a donation amounting to over \$6,000, for the purpose of establishing free baths, but, as its managers did not care to undertake this work, they very generously turned over this fund to the Association, and at the same time offered a suitable site in the midst of the East Side tenement house district, for the construction of the baths. The building, exclusive of the land, has cost

about \$25,000, and its facilities are capable of accommodating nearly 1,000 bathers daily. A charge of 5 cents is ordinarily made for each bath, including the use of a good towel and the present of a small cake of soap, but provisions have also been made by which the very poorest can obtain their baths free. As the male and female departments are entirely distinct throughout, women and girls can bathe at all times, and not merely on certain days or at special hours.

Dr. Abram Du Bois, one of the most honored members of the profession in New York, died on the 29th of August, in the 82d year of his age. He was one of the most generous benefactors that the Academy of Medicine ever had, and the large and handsome hall in the rear of the old building on 31st street, with a meeting room below and accommodations for the library above, was entirely his gift. He was one of the founders of both the New York State and County Medical Associations, and was deeply grieved at the course of the Academy of Medicine in repudiating the National Code of Ethics. At one time he signified his willingness to give the handsome sum of \$60,000 for the construction of a permanent building for the State Association in this city, provided a certain amount was subscribed by other Fellows of the Association; but the desired fund was never raised.

P. B. P.

NECROLOGY.

DR. ABRAM DUBOIS, of New York City, died August 29, aged eighty-one years. From the time of his graduation, in 1835, at the College of Physicians and Surgeons, to his retirement from active practice, about 1880, Dr. Du Bois was noted for his devotion and generosity toward every worthy professional undertaking. The Academy of Medicine, in one year, received from him \$3,000 for library purposes. He was a pioneer in specialism in New York, giving his chief attention to ophthalmology from the outset of his professional life. He was for many years the senior consulting surgeon to the Eye and Ear Infirmary, and a liberal benefactor thereto.

THE POINT OF SELECTION IN PARACENTESIS OF THE ABDOMEN.—In an editorial in the *International Journal of Surgery*, May, 1891, the question of paracentesis abdominis is discussed, and a case of Frzebicky's (*Archiv. für klinische Chirurgie*) quoted, in which profuse hæmorrhage occurred from a puncture made at Munro's point, which is midway between the umbilicus and the anterior superior spine of the ilium. If the puncture is made at this point a considerable number are apt to be followed by hæmorrhage. Directly in the linea alba is the best place, and if this is not possible it should be made in the outer half of a line drawn from the umbilicus to the anterior superior spine of the ilium.

MISCELLANY.

THE INTER-CONTINENTAL AMERICAN MEDICAL CONGRESS.—Dr. J. C. LeHardy, member of the Auxiliary Committee of the Inter-Continental American Medical Congress for Savannah, Ga., writes to Dr. C. A. L. Reed, Chairman of the National Committee, as follows: If money can be secured we ought to make the occasion an epoch in the history of medicine. It seems to me that the distinct feature of this Congress should be to have as complete a display as possible of the medicinal plants and medicinal preparations, of the surgical instruments and appliances, electric and other machinery, of all scientific instruments and devices *used at this time* in the different parts of North and South America and islands surrounding, or, if possible, in the whole world, by the savages and semi-civilized, by the negro slaves and those that have been freed, by backwoods quacks and doctors and by those who have attained the highest grade in civilization and knowledge. Competent persons should be employed as soon as possible to collect these among the Indians and from the Negroes on the Atlantic Coast and in Central and South America.

Dr. Reed will lay the suggestions before the National Committee which meets in St. Louis, October 14th.

THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.—Programme of the Fourth Annual Meeting, to be held in the hall of the Academy of Medicine, 17 West Forty-third street, in the City of New York, Thursday, Friday and Saturday, September 17, 18 and 19, 1891. All persons interested are most cordially invited.

First Day, Thursday, September 17, 1891.

Business meeting at 9:30 o'clock A.M., for Fellows only.

Morning session, 10 o'clock.

1. Address of Welcome and Response, Drs. Roosa and Rohé.
2. Post Partum Hæmorrhage; Its Etiology and Treatment; Dr. Aug. P. Clarke, Cambridge.
3. Removal of the Kidney for Disease, with Cases, Dr. William J. Asdale, Pittsburgh.
4. Another Method of Palpation of the Kidney, Dr. Robert T. Morris, New York.
5. Intra-Uterine Irrigation after Labor, Dr. Lewis S. McMurtry, Louisville.
- Afternoon Session, 3 o'clock.
6. Is a Child Viable at Six and a Half Months? Dr. Llewellyn Eliot, Washington.
7. Some of the Dangers Incident to Delay in Operating for Uterine Myomata, Dr. Isaac S. Stone, Washington.
8. How Should We Proceed when Abdominal Tumors are Complicated by Pregnancy? Dr. James F. W. Ross, Toronto.
9. Thoughts Pertaining to Maternal Impressions During Gestation, Dr. William S. Stewart, Philadelphia.
- Second Day, Morning Session, 10 o'clock.
10. Removal of the Uterine Appendages, with Results, Dr. Milo B. Ward, Topeka.
11. A few Abdominal Sections Selected from my own Work, Dr. William H. Myers, Fort Wayne.
12. The Prevention of Secondary Peritoneal Adhesions by an Aristol Film, Dr. Robert T. Morris, New York.
13. The President's Annual Address (12 o'clock M.), Dr. Adam H. Wright, Toronto.
- Afternoon Session, 3 o'clock.
14. Asepsis in Abdominal and Pelvic Surgery, Dr. William H. Wathen, Louisville.

15. A Case of Cholecystotomy and Cholelithotripsy; Death from La Grippe on the 21st day, Dr. William Wotkyns Seymour, Troy.

16. Report of Cases of Cholecystotomy, with Special Reference to the Treatment of Calculus Lodging in the Common Duct, Dr. A. Vander Veer, Albany.

17. Femoral and Ventral Hernia in the Female, Dr. Henry O. Marcy, Boston.

Business Meeting at 7:30 o'clock for Fellows only.

Third Day, Morning Session, 10 o'clock.

18. Some Moot Points in Ectopic Gestation, Dr. N. O. Werder, Pittsburgh.

19. Ectopic Pregnancy; When Shall we Operate? Dr. Rufus B. Hall, Cincinnati.

20. Trendelenburg's Posture in Gynecology; With Demonstrations, Dr. Florian Krug, New York.

21. Treatment of Minor Lacerations of the Perineum, Dr. George R. Shepherd, Hartford.

22. Peritonitis, Dr. Mordecai Price, Philadelphia.

Afternoon Session, 3 o'clock.

23. Peritonitis, Dr. Edwin Ricketts, Cincinnati.

24. Manual Rectification of Certain Malpositions of the Head in Labor, Dr. William H. Wenning, Cincinnati.

25. A Plea for Early Hysterectomy and Puerperal Hysterectomy, Dr. Joseph Price, Philadelphia.

26. Observations on the Surgical Management of Pelvic Abscess, Dr. Charles A. L. Reed, Cincinnati.

27. The Essential Question of Drainage in Pelvic Surgery, Dr. Lewis S. McMurtry, Louisville.

The Windsor Hotel, Fifth Avenue and Forty-seventh Street, will reduce its regular rates to Fellows and guests of the Association.

AUSTIN DISTRICT MEDICAL SOCIETY.—The sixteenth quarterly meeting of the Austin District Medical Society will meet at Austin, Tex., Thursday, September 24, 1891.

Officers: J. W. McLaughlin, M.D., Austin, President. W. A. Ellison, M.D., Manchaca, First Vice-President. J. W. Hamilton, M.D., Lampasas, Second Vice-President. T. J. Bennett, M.D., Austin, Secretary and Treasurer.

Censors: T. O. Maxwell, M.D., Fiskville, Chairman; S. E. Hudson, M.D., Round Rock; F. R. Martin, M.D., Kyle; A. N. Denton, M.D., Austin; J. A. Davis, M.D., Austin; H. H. Thorpe, M.D., Liberty Hill.

The Society will meet in Medical Hall, and will be called to order promptly at 9:30 A.M.

Programme, Morning Session:

1. Reading of Minutes.

2. Application for Membership.

3. "Syphilis," by Dr. C. O. Weller; discussion opened by Drs. Matt. M. Smith and H. H. Thorpe.

4. "The Advantages of the Supra-Pubic Operation in Cystotomy," by Dr. W. M. Cunningham; discussion opened by Drs. W. J. Matthews and J. W. Hamilton.

Afternoon Session, 2:30 o'clock.

5. "Acne," by Dr. F. E. Daniel; discussion opened by Drs. Fannie Leake and L. H. Hardy.

6. "Biliousness," by Dr. W. E. Shelton; discussion opened by Drs. J. A. Davis and C. A. Danforth.

7. Voluntary Papers.

8. Verbal Reports of Cases.

9. Unfinished Business.

10. New Business.

J. W. McLAUGHLIN, President.

T. J. BENNETT, Secretary.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from August 29, 1891, to September 4, 1891.

Capt. Adrian S. Polhemus, Asst. Surgeon, granted leave of absence for one month, to take effect on or about September 3, 1891.

Surgeon J. V. D. Middleton, U. S. A., is granted leave of absence for fifteen days.

Major James P. Kimball, Surgeon U. S. A., is granted leave of absence for twenty-five days.

PERIMETRIC OBSERVATIONS ON THE INFLUENCE OF ESERINE AND IRI- DECTOMY IN CHRONIC GLAU- COMA.

Read in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY G. E. DE SCHWEINITZ, M.D.,

OPHTHALMIC SURGEON TO THE PHILADELPHIA AND CHILDREN'S HOSPITALS; OPHTHALMOLOGIST TO THE INFIRMARY FOR NERVOUS DISEASES; LECTURER ON MEDICAL OPHTHALMOSCOPY IN THE UNIVERSITY OF PENNSYLVANIA.

The best treatment for chronic glaucoma has often been discussed, but even at this time considerable difference of opinion exists in regard to the most satisfactory method, while the prognosis of the disease, depending as it does upon many factors, is always a doubtful quantity even after the most skilfully performed surgical interference. Most surgeons will, I think, subscribe to the doctrine of Dr. Bull, who says, "It seems to be our duty to operate in cases of chronic progressive glaucoma, and the earlier the better." It is presupposed that the patient has previously been warned of the nature of this disease to progress towards blindness and, as Priestley Smith has said, of the uncertainties which beset the operation. When a case of chronic glaucoma is under observation and the surgeon is weighing the chances for and against operation, it becomes necessary not merely to test the acuity of vision, but to have frequent information in regard to the field of vision, although, no doubt, it is perfectly true, as Dr. Bull further has said, that the condition of the field of vision is no constant guide either in forming a prognosis as to the progress of the disease or in deciding as to the time of operation. The picture of chronic glaucoma is a very familiar one, and we are all familiar with the so-called simple varieties of the disease in which the front of the eye exhibits practically no signs of disease, the anterior chamber may be of good depth and the iris prompt in its reactions to light and myotics, in which there is sometimes never any perceptible increase of tension, or this is only temporary in its character, but in which there is a shallow excavation of the

disc, glaucomatous in its type, some decrease in vision, and contraction of the field. Since the days of Laqueur the use of myotics in the treatment of glaucoma has formed an important part of the treatment of the therapeutics of this disease, and there can be no question of the value of eserine and pilocarpine in acute and subacute forms of glaucoma, where for any reason it is necessary to delay operation, or where it may be wise to attempt a reduction of the tension before an operation is undertaken. It is very definitely ascertained that a myotic by contracting the pupil lowers the tension, if this be abnormally raised, and that by the same action the meshes of Fontana's space are widened, helping in the absorption of the fluid. It is, however, also ascertained that strong solutions of eserine, especially if frequently repeated, are likely to irritate the ciliary body and cause a spasm of accommodation; indeed iritis itself is known to follow the too vigorous application of a strong solution of a drug of this character. The employment of eserine or pilocarpine in chronic simple glaucoma, especially if there is no decided increase of tension, and if the anterior chamber is moderately deep, does not seem to present itself as favorably as in those instances, where there is a distinct rise of tension, narrowing of the anterior chamber, swelling forward of the lenticular system, and probable blocking of the filtration angle. Nevertheless it is a very universal custom to prescribe eserine or pilocarpine in such cases while the surgeon is watching the disease and making up his mind as to the propriety of operative interference. Perhaps sometimes he is induced to give this drug by the feeling that he has applied a salve to his conscience at the same time that he has ordered a drug which is set down as one of the methods of treatment in glaucoma, although he probably believes with Nettleship that eserine, except very rarely, cannot stop the progress of chronic glaucoma. The following cases are reported as examples of the value of this drug in the management of chronic glaucoma when operative interference was declined, and illustrate graphically the influence of the drug in widening and maintaining the field of vision, and also its occasional entire insufficiency to control the desire.

Case 1. Chronic Simple Glaucoma; No sub-

acute Attacks.—W. G. N., a man aged 72, an American by birth, applied for treatment November 11, 1890; has always been dyspeptic. He has had no recent severe illness except a pleurisy from which complete recovery has taken place. Some months ago his right eye appeared to him to be dim; he has never had any pain or any redness of the eye, "but thought his glasses were not right." In the right eye the pupil is prompt, the anterior chamber of moderate depth, the iris of good color, the cornea clear and not anæsthetic; the optic disc is a small, vertical oval with a deep cup ($-2.D.$) passing completely to the edge on the temporal side and nearly to the margin of the nasal half. The disc is surrounded by a semi-atropic crescent on the temporal side; there is a strong venous but no arterial pulse; $T + ?$; a few striæ in the anterior cortex of the lens. In the left eye, cornea, iris and pupil of the same character as just described; some striæ in the lens; an oval disc, rather gray but not cupped; there is a venous pulse. The field of vision of the right eye at this date is represented in diagram 1, namely, distinct contraction of about twenty-five degrees upon the nasal half, and a narrow rim of contraction above and in the upper temporal portion. The field of vision of the left eye was normal in all respects. The patient's refraction was as follows:

O. D. $+ 1. \bigcirc + .50$ axis $V \frac{2}{3} 0$. O. S. $+ 1. \bigcirc + .75$ axis $H \frac{2}{3} 0$.

Eserine, gr. $\frac{1}{24}$ to the ounce was ordered three times a day. One week later the vision remained nearly the same ($\frac{2}{3} 0$) and the field of vision about the same with perhaps a slight increase of the contraction upon the nasal side. (Diagram 2). The strength of the eserine was now doubled, namely, $\frac{1}{12}$ of a grain to the ounce. One month later, December 10, 1890, the field presented the characters seen in diagram 3, namely, the same contraction above and to the upper temporal side but distinctly less contraction to the nasal side. There was no pain or discomfort, and the patient pursued his usual occupation, necessitating a deal of eye work.

Again, about a month later, January 3, 1891, he reported, stating that for some days his eye had felt uncomfortable, not exactly a pain but a dull aching sensation with a curious feeling as if an insect was crawling back of it, and with increase in his dim vision. He had been somewhat irregular in the use of his eserine. The vision then was O. D. $\frac{2}{7} 0$, O. S. $\frac{2}{2} 0$, and the field of vision as seen in diagram 4, namely the same peripheral contraction above and to the upper temporal side with a contraction which now extended more decidedly below and in the lower and inner quadrant; the eserine of the same strength (gr. $\frac{1}{12}$ to the ounce) used frequently every three or four hours for a week, then gradually lessened to three times a day. In a week

the field had returned to almost exactly the appearance it presented in diagram 3. The treatment was continued, the patient occasionally taking *nux vomica* and *strychnia* in addition, and on the 16th of March, or four months after he was first seen, the vision was $\frac{2}{3} 0$ as at the original visit, and the field presented the characters seen in diagram 5, namely, the peripheral contraction above and in the upper temporal portion having disappeared, and only a slight nasal contraction remaining. This character of field obtains at the present time. It may be stated that this patient was seen by Dr. Norris about six months before I examined him, and the same conditions were

Adapted to the "M. B." Perimeter.

present which I had noted at his first visit. He was given eserine at that time and advised to use it, but he was not at all regular in its employment. We may hence say that for nearly a year this patient has used eserine off and on, and that for five months of that time he has instilled a so-

lution of the drug with pretty constant regularity. I would note as points of interest the gradual widening of the field of vision in all particulars in so much that there is complete restoration on the upper and temporal portions, and the only remaining portion of contraction being found upon the nasal side which, at its widest part, is about fifteen degrees. There has never

this case; in fact, the tension has always been a doubtful + so that it seems to show that even in the absence of a decided elevation of intraocular tension eserine has some power in improving the nutrition of the eye and causing a restoration in a contracted field. The slight tonic doses of strychnia and nux vomica, which this patient took from time to time, can scarcely be account-

been any subacute attack, although on one occasion a dull, aching pain was associated with a depreciation of central vision and an increase in the contraction of the visual field which again widened out under an increased frequency in the use of the drug until the favorable result noted graphically in diagram 5, was obtained and is maintained. If there is any favorable time for operation it certainly is present now. This has been advised and will be done provided consent is obtained. I would particularly point out that there has never been any increase in tension in

able for the favorable result, although I am convinced that the accuracy of the statement of Dr. Henry D. Noyes, that strychnia in high doses produces temporary improvement in vision, perhaps in those cases especially which as he says border closely upon simple atrophy of the nerve.

2. *Chronic Glaucoma; Numerous Subacute Attacks Occurring during the course of the Disease, with Diagrams of the Fields of Vision Illustrating the Effect of Eserine in Controlling these Exacerbations.*—Mrs. E., aged 50, an American by birth, came for treatment in September, 1888, complaining simply of dimness of vision in the right eye and inability to procure suitable glasses; headache and pain of any type was denied; the general health was perfect. The vision of the right eye was $\frac{1}{40}$; of the left $\frac{1}{30}$. In the right eye the cornea was slightly anæsthetic, the anterior chamber shallow, the disc round, excavated to its edges, especially deep above with an overhanging margin, beyond which and to the nasal side the papilla was surrounded by a buff-colored rim, in its turn encircled by a broad, halo-like band; T + 2; the iris was not atropic. In the left eye the anterior chamber was shallow, but no anæsthesia of the cornea; the disc oval, gray-red; a small, rather sharp, central excavation, not shelving; the veins full but not pulsating. The following results were procured by correction:

O. D. + 2.5 C + .65c axis $15\frac{1}{2}^{\circ}$. O. S. + 2.25s C + .65c axis H $\frac{1}{5}$.

This was given for constant wear and eserine,

gr. $\frac{1}{2}$ to the ounce, ordered, inasmuch as iridectomy was declined. The patient up to the present date has used this drug almost continuously, except on a few occasions, when a slight conjunctivitis appeared and it was discontinued or had substituted for it pilocarpine. She has had a number of attacks of subacute glaucoma, the vision sometimes sinking to $\frac{2}{200}$, the cornea becoming slightly steamy, distinctly anæsthetic, and the episcleral vessels coarsely injected, the tension rising to + 2 or 3. All operation has been systematically declined and in all instances

traction, the limitation producing a band of darkened area varying from 20 to 25 degrees in breadth, surrounding the preserved field of vision. Diagram II represents the field of vision on the day of one of the subacute attacks; eserine one quarter of a grain to the ounce was instilled every two or three hours. It will be observed that the field of vision under these circumstances assumes the type of a left lateral hemianopsia with concentric contraction of the preserved area. Diagram III represents the field of vision after twenty-hours' use of such eserine,

reasonable recovery has been produced by the use of eserine increased in strength and in frequency of application over and above what was continuously used. At present the best vision in the right eye is $\frac{2}{40}$; in the left eye $\frac{2}{20}$. Diagram I represents the field of vision as it was found at the original visit, September, 1888, and as it has remained almost exactly on all occasions except during the exacerbations. It will be observed that it is of that form known as a concentric con-

traction, the limitation producing a band of darkened area varying from 20 to 25 degrees in breadth, surrounding the preserved field of vision. Diagram II represents the field of vision on the day of one of the subacute attacks; eserine one quarter of a grain to the ounce was instilled every two or three hours. It will be observed that the field of vision under these circumstances assumes the type of a left lateral hemianopsia with concentric contraction of the preserved area. Diagram III represents the field of vision after twenty-hours' use of such eserine,

diagram IV, or, in other words, about the same as it was two and one-half years ago, there being only a slight loss of less than ten degrees upon the nasal side. There have been a number of subacute attacks in all instances characterized by the symptoms just described, sinking of the vision, steaminess and anæsthesia of the cornea, increase in tension, rapid reduction of vision usually to $\frac{2}{40}$ and loss of the nasal half of the field, and in all instances the sequence of events has been that which has just been described. It is proper to state that during the attacks full doses of chloral were also used, and, as we know, this drug is credited with an influence upon increased intraocular tension, and that the patient has continuously taken either nux vomica or strychnia, but never in very full doses. The points of interest in this case are its long continuance without very great loss in vision, the frequent subacute attacks which have resulted in reasonable cure under the influence of eserine, the form which the fields of vision assume in one of these attacks, namely, that of almost complete left lateral hemianopsia, and which under the influence of the drug gradually widens out until the lost nasal field is restored, and the entire field practically assumes the same proportion which it had before the attack. In fact, as has just been shown at the last examination, about a month ago, in spite of some loss of the central vision ($\frac{2}{40}$ as compared with $\frac{1}{5}$ at the original visit) the field is quite as large as it originally was, although not exactly of the same oval shape. The indication for eserine in this case is evidently very much more marked than in the one just reported, because in the first place more or less tension was always present, the anterior chamber was narrow, and in the second place during the exacerbations there was distinct rise in the intraocular tension. I cannot help believing that the eserine has been influential in preserving to this woman for more than two years the sight which she has.

Case 3. Chronic Glaucoma: Steady Progress Towards Blindness in Spite of Eserine and Full Doses of Strychnia; No Acute Attacks and No Pain.—James M., aged 60, of Irish birth, in January, 1890, began to notice before the one eye a spot which resembled the blue blossom on a blade of grass; he never had any iridescent vision nor was there pain or headache. He seems to have had no treatment for his eye until he came in September, 1890, or almost nine months later, when the following facts were ascertained: The dark spot no longer bothers him, but the vision has much depreciated; he is weak, somewhat nervous; has a chronic bronchitis; has used liquor frequently, of which the injection of the superficial capillaries in the nose and cheek give evidence. In the right eye the vision without correction was $\frac{2}{40}$; in the left eye $\frac{2}{100}$. In the right eye the pupil was prompt, the disc a horizontal

oval, gray, with a scleral ring all around, the edges slightly veiled; no excavation and the choroid woolly. In the left eye the pupil very sluggish and slightly larger than its fellow; an oval disc, a shallow glaucomatous cup, passing entirely to the edge, which is slightly greenish all around, and beyond a halo-like annular absorption band assuming a triangular shape above; the veins very tortuous, the choroid woolly and

disturbed; the tension distinctly +. The field of vision is represented in diagram I, showing practically entire loss of the nasal half, and a somewhat trowel-shaped preservation upon the temporal side. Eserine, a sixth of a grain to the ounce, was given, and the patient reported very irregularly, having declined operative interference. On January 19, 1891, the vision in the right eye was $\frac{2}{40}$ without correction, but with correction, namely, + 1. \odot +.90 axis 152° ; in the left eye $\frac{2}{60}$ barely. The field of vision is represented in diagram II, namely, entire loss of the nasal half and a very small irregular patch

of preservation upon the temporal side. Eserine or pilocarpine, the latter in twice the strength of the former, were used continuously, and the patient took sometimes iodide of potash and sometimes very full doses of strychnia. A month later the vision had declined to counting fingers at two feet, the lens showed numerous, fine dot-like opacities, and the dirty green color of the disc had increased. Still a month later the field of vision is represented in diagram II, a still further increase of the blind area having taken place, so that now only a patch fifteen degrees wide at its greatest diameter remains. Last month the condition was about the same, fingers

being counted eccentrically at about one foot. Thus far the right eye has not shown any glaucomatous signs, although he occasionally sees black spots in the field of vision. This is a good example of the steady progress of chronic glaucoma towards blindness in spite of medicinal treatment, and the fields of vision illustrate this well. Whether the process could have been stayed when the man first reported, in September, 1870, by an operation, it would be purely speculation to answer. Even at that time the contraction of the field of vision was dangerously close to the fixing point, and perhaps that unfortunate result which has followed iridectomy in cases of this kind would here also have occurred.

Case 4. Visual Fields Illustrating the Effect of Iridectomy in Simple Chronic Glaucoma.—Mrs. X., an American by birth, had passed her sixtieth year, and applied for treatment in June, 1889, complaining of loss of vision, especially in the upper portion of the field of the right eye, a frequent desire to change her reading glasses, dull aching pain in the eyeballs, and occasional neuralgia through the trigeminal distribution. The patient has chronic dyspepsia, is excessively nervous, and often the subject of insomnia. The

vision in each eye was $\frac{30}{40}$; this rose by means of a correction as follows:

O. D. + .50 \odot + .50 axis 15 $\frac{20}{15}$. O. S. + .50 \odot + .50 axis 165 $\frac{20}{15}$.

The pupils were small and active, the anterior chamber shallow, the irides not atrophic. In the right eye the disc was a horizontal oval with a halo-like band surrounding it, and a complete shallow glaucomatous cup; pulsation of the vessels was readily induced by pressure. In the left

eye the disc was oval, its axis 105 degrees, a deeper but not quite complete excavation, and a broad band surrounding the papilla. In the right eye T. + 1; in the left eye T. + ?. The field of vision showed in the right eye somewhat concentric contraction and loss of the upper and inner quadrant; in the left eye slight peripheral contraction. The patient was fully corrected and put upon eserine in the usual dose. Frequent examinations of the fields of vision, as well as of the central vision, were made at short

intervals. Very little change took place for the worse until about the first of the year 1890, then, after a prolonged siege of nursing followed by a pretty sharp illness (bronchitis), there was marked depreciation of vision, which fell to $\frac{2}{30}$ in the right eye, but remained at $\frac{2}{30}$ in the left. Eserine and pilocarpine were alternately used, and iridectomy advised. This was declined, and the patient did not make up her mind to submit to operation until June, 1890. Then, as the vision again failed, a broad peripheral iridectomy by the upward section was made on the right eye. Diagram I represents the field of vision of the right eye nine days before the operation, a form which had varied very little during the entire course of the disease. Diagram II represents the first field of vision taken after the iridectomy was performed; that is, eighteen days subsequent to the operation, at which time the central vision was $\frac{2}{40}$ — and the astigmatism exactly doubled,

been no increase in the glaucomatous process. I would note, then, as points of interest in this case, that the iridectomy checked the process, doubled the astigmatism, caused gradual but none the less distinct improvement in the visual field, with a corresponding improvement in the central vision, and finally, was the means of a partial restoration of perception in a previously entirely darkened area. It is proper to state that this patient has been taking almost continuously digitalis, nux vomica and strychnia, in the hope of increasing the circulation in the optic nerve and improving its function. It is quite possible that the good result may have been contributed to by these drugs.

DISCUSSION.

DR. EDWARD JACKSON reported a case of glaucoma of ten years' standing in which, about two months ago, there was a violent outbreak, the patient being a feeble old man, 90 years of age. He made a paracentesis and instilled eserine, and the pain disappeared and has remained so until now, with reduction of tension from + T. 3 to normal.

DR. G. A. ASHMAN called attention to the danger of deferring the operation too long by using eserine for temporary relief, and finally, when done, it is not satisfactory. Thinks bad results now are largely due to this fact. Eserine is only good in the beginning, and even then the effect is only temporary. Cases are rare where any permanent good effect comes from the use of eserine.

DR. EUGENE SMITH: I am in the habit of combining sclerotomy with the use of eserine or pilocarpine in treatment of all cases of chronic simple glaucoma. I make either simple sclerotomy after the method of Wecker, of Paris, or a double sclerotomy with two stop keratones—one in each hand—and I find better results when sclerotomy is combined with eserine, than with eserine alone.

DR. J. WALTER PARK, Harrisburg, Pa.: I can bear testimony to the remarks of Dr. de Schweinitz regarding the value of weak doses of eserine and pilocarpine in chronic glaucoma, having at present some cases under treatment bearing me out in what I say. During my stay at Mansfield Hospital, 1889, I observed with Dr. Morton and others cases of four years' standing of chronic glaucoma treated with weak doses of eserine, and which, in December, 1889, still had the same visual field. Iridectomies in chronic glaucomas were not followed by beneficial results, as a rule.

DR. RANDALL wished to emphasize the value of very weak solutions. Its success will often be as great as that of stronger solutions, and it is borne for many months without conjunctival irritation, although he had used it much in other conditions as well as glaucoma.

requiring now a + 1 cylinder with its axis at 15 for its correction. It will be noticed that the field is almost exactly the same as that taken nine days previous to the operation. Diagram III represents the field of vision in December, 1890, or almost exactly six months after the operation. It will be observed by comparing it with the other charts, that the preserved field has widened, that the area of lost vision is now occupied by an irregular triangular patch 30 degrees in its length, and varying from 5 to 30 degrees in its width, situated directly upward, like an island in the dark area. In this patch the patient appreciates the passing of an object without being able to distinguish its quality. Thus, a circle of white on a black background is simply appreciated as an object, not as a circle of white. The dark area no longer touches the fixing point above, but there is an area of about 10 degrees in which the vision has returned. The central vision is now $\frac{2}{40}$ full and $\frac{2}{30}$ partly. There has

DR. S. C. AYRES only uses $\frac{1}{10}$ gr. of eserine to the ounce. Finds strong solutions harmful. He reported a case of glaucoma in which iridectomy was made in one eye and eserine used in the other, and after using eserine two and a half years, $\frac{1}{10}$ gr. to the ounce, the condition of the eye was such as to make the result quite satisfactory.

DR. DE SCHWEINITZ, in conclusion, said that he subscribed entirely to the doctrine that operation should be done in chronic progressive glaucoma, but eserine must occasionally be used temporarily, or when consent was lacking. He endorsed the value of weak solutions oftener, and the alternate use of eserine and pilocarpine. He referred to the physiological action of chloral upon intraocular tension.

DR. G. E. DE SCHWEINITZ referred to the difference of opinion existing in regard to the most satisfactory method of dealing with chronic glaucoma, and agreed with those surgeons who believe that it is proper to operate in cases of chronic progressive glaucoma after the patient has been properly warned in regard to the nature of the disease and the uncertainties which beset surgical interference. Inasmuch, however, as under certain circumstances it was impossible to operate owing to the lack of assent, the physiological action of eserine and pilocarpine on the eye was discussed, and a series of diagrams exhibited indicating the influence of these drugs upon chronic simple glaucoma. The first case was one of the simple variety of the disease, without sub acute attacks, and without any special rise in tension or alteration in the anterior portion of the eye. His charts showed gradual widening of the fields of vision in all particulars, so much so that there was a complete restoration of a previously lost portion of contraction being found upon the nasal side, which also had lessened. This patient was under observation for nearly a year. The chief interest attaching itself to the case was that there had never been any increase in tension, although the typical appearances of a glaucomatous disease were present in the eyeground and it seemed to demonstrate that even in the absence of decided elevation of intraocular tension, eserine has power to improve the nutrition of the eye and cause a restoration in a contracted field. In a second case of chronic glaucoma with numerous sub-acute attacks the points of interest were the long continuance of the disease two and one-half years, without very great loss of vision, the frequent subacute attacks which resulted in reasonable cure under the influence of eserine, the form which the fields of vision assumed in one of these attacks, namely, that of almost complete left lateral hemianopsia, which under the influence of the drug gradually widened out until the lost field was restored and the entire field assumed practically the same proportions which

it had before the attack. In a third case diagrams of the fields of vision were exhibited showing in spite of eserine the steady progress of chronic glaucoma towards blindness, until there was only a small patch about ten degrees wide remaining on the temporal side. The effect of iridectomy in simple chronic glaucoma when it yields a good result was graphically illustrated by a series of charts before and after iridectomy. The original loss of the field had been complete in the supero nasal quadrant, while six months after the iridectomy the central vision remained as good if not a little better, than preceding this, while there was a gradual improvement in the visual field and a partial restoration or perception in a previously entirely darkened area. Incidentally Dr. de Schweinitz referred to the value of full doses of strychnia in temporarily controlling chronic glaucoma, and also spoke of the physiological action of chloral in full doses in lessening intraocular tension, one of his cases having apparently been benefited in this way by the drug.

THE STATISTICS AND LESSONS OF FIFTEEN HUNDRED CASES OF REFRACTION.

Read in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY GEORGE M. GOULD, M.D.,

OPHTHALMOLOGIST TO THE PHILADELPHIA HOSPITAL, PHILADELPHIA, PA.

As indicative of the tremendous importance of refraction in modern ophthalmic practice—at least in that of mine—I note that, in the time covered by my case records, 93 per cent. of all cases has, according to my judgment, required correction of ametropia, while but 7 per cent. required treatment of diseases of the eye alone.

Comparison of my figures with those, *e.g.*, of European ophthalmologists, will hardly yield satisfactory results, because every case here included was tested with the patient's eyes under a mydriatic except where presbyopia was so far advanced as to make the drug unnecessary.

The patients coming to the oculist are doubtless more frequently ametropic than people that do not come, and yet probably a very small percentage of the general community is emmetropic. Of all my patients, but four have been emmetropes—*i. e.*, about one fifth of one per cent.

As pointing to the disproportionate incidence of ametropic irritations and injuries among males and females, I find that 76 per cent. of my cases have been girls and women; but 24 per cent. boys and men. I take it that this is not to be construed as meaning that females are more frequently ametropic than males, or that their ametropia is greater in degree. Part must be ascribed to the greater use by women of the eye

at near range demanded by their manner of life and occupation, part to their greater sensitiveness of nervous organization, part to their lessened resisting power, etc.

Twenty-four per cent. of all my cases have been presbyopes, but these corrections have been left entirely out of the present count.

In order to limit my statistics to refraction work alone, I have thrown out all cases in which there was intercurrent disease of the fundus or media of the eye that might violate the refraction result; all cases of aphakia; those with amblyopia not definitely connected with refraction; all in which systemic disease would possibly account for or change the refraction error. After thus setting aside such cases as these, I have remaining 2,866 eyes to form a basis of my study. The general results are shown in Table I.

TABLE I.—GENERAL REFRACTION OF 2,866 EYES.

Variety of Error.	Eyes.	Per Cent. of H.	Per Cent. of All.
Simple Hyperopia	373	17.	13.
Simple Hyperopic Astigmatism	172	7.	6.
Hyperopia, with Astigmatism	1,680	76.	58.
Total Hyperopic	2,225	100.	77.
		Per Cent. of M.	
Simple Myopia	63	9.	2.2
Simple Myopic Astigmatism	79	12.	2.8
Myopia, with Astigmatism	509	79.	18.
Total Myopic	641	100.	23.0
Grand Total	2,866		100.0

Thus more than three-fourths of all my cases have been hyperopic, and of this number three-fourths have been also astigmatic. Relatively to its own group, the cases of simple hyperopia have been nearly twice as numerous in hyperopia as those of simple myopia in myopia; the percentage being reversed in simple astigmatism; the percentage of each combined with astigmatism is almost identical. The tabulation of the hyperopic cases, not including astigmatism, is given in Table II.

Thus more than one third of all hyperopes and one-fourth of all eyes had an error of 0.50 D. or less, and nearly two-thirds of all hyperopes and nearly one-half of all eyes had an error of 1 D. or less. I have found it wise to correct a large proportion of these small errors.

Comparison of the annexed Table III of myopic eyes shows the foreseen result—the greater incidence of high degrees in myopia. The degrees above 5 D. are 17 times as numerous in myopia as in hyperopia. While 12.5 per cent. of hyperopes had an error above 2 D., 34.5 per cent. of myopes had the corresponding defect.

The percentages of each variety of astigmatism, arranged in groups, are given in Table IV.

Included in this table, without separation, are

TABLE II.—REFRACTION OF 2,053 HYPEROPIC EYES, ASTIGMATISM NOT INCLUDED.

172 cases of simple hyperopic astigmatism and 79 cases of simple myopic astigmatism. There

are similarly included 57 cases of mixed astigmatism. The cases of simple hyperopic astigmatism, as compared with all cases of hyperopic astigmatism, are less than 10 per cent.; those of simple myopic astigmatism, as compared with all of myopic astigmatism, about 13 per cent. Low

degrees of astigmatism of the hyperopic variety are relatively more numerous than of the myopic, whilst the high degrees are still more numerous in the myopic.

The axes of astigmatism are shown in Table V.

TABLE V.—AXES OF 2,440 ASTIGMATIC EYES.

Hyperopic.	Eyes.	Per Cent. of H. Axes.	Per Cent. of All Axes.
Axis 90°	953	51.4	39.0
Axis 180°	267	14.5	11.0
Symmetrical (not 90° or 180°)	292	15.8	12.4
Unsymmetrical	340	18.3	13.9

Unsymmetrical	168	28.4	6.8
Total	588	100.0	100.0

As the question of symmetry and asymmetry is of much interest, I add another table, setting forth in further detail the 254 cases of non-symmetrical axes. Included in Table V are 40 cases (80 eyes), in which the axis of one eye was 90°, and of the other eye, 180°. Those cases in which

one axis was either 90° or 180°, and the axis of the fellow-eye neither 90° nor 180°, are, in Table V, included among the unsymmetrical axes, and further differentiated in Table VI.

TABLE VI.—UNSYMMETRICAL AXES—254 CASES.

Hyperopic.	Cases.	Per Cent. of Unsymmetrical H. Axes.	Per Cent. of all Unsymmetrical Axes.
One Axis 90°	70	41.2	27.6
One Axis 180°	25	14.7	9.8
Both Axes same (not 90° or 180°)	8	4.7	3.2
Sundry (not included in above)	67	39.4	26.4
Total	170	100.0	
Myopic.		Per Cent. of Unsymmetrical M. Axes.	
One Axis 90°	9	10.7	3.6
One Axis 180°	32	38.0	12.3
Axes same (5-5, 10-10, 20-20)	3	3.5	1.2
Sundry (not included in above)	40	47.6	15.9
Total	84	100.0	100.0

In studying these cases of unsymmetrical axes I have been interested in trying to discover some law or tendency to a law to which they would conform. We know that in all hyperopic astigmatism the primary law is a tendency of the axis toward polarity at 90°. If we add to those cases where both axes are at 90°, those asymmetrical instances in which one axis only is at 90°, we get a total of 1,023 hyperopic eyes, or 55 per cent., with astigmatic axes at 90°. If to this number we add all the myopic axes at 90°, we have a total of 1,122, or 46 per cent. of all astigmatic eyes. In the same way the myopic axes find their preferential pole at 180°, and adding to these 226 symmetrical cases the 32 in which one axis is at 180°, we have a total of 258 eyes, or 44 per cent. of all myopic axes. Adding, again, the 267 symmetrical hyperopic axes at 180° and the 25 unsymmetrical, we have a total of 550 eyes, or 22 per cent. of all astigmatic eyes, with the axis at 180°. Hyperopic axes are more apt to be at 90° than myopic axes are at 180° as 5 is to 4, *i. e.*, they are 20 per cent. more frequent; and any axis of astigmatism whatsoever is more than twice as liable to be at 90° as it is to be at 180°, the proportion being as 46 is to 22. Over two-thirds (68 per cent.) of all astigmatic eyes have their axes either at 90° or 180°. It is also seen that there is a much greater tendency to unsymmetrical axes in myopia than in hyperopia, the ratio being as 28 is to 18, or 65 per cent.

Can we find any law governing the unsymmetrical axes? Both the hyperopic and myopic varieties appear to be similarly lawless. Take the hyperopic class: In 25 cases with one axis at 180° there are six instances where the fellow axis is twice alike, the remaining 19 being all different one from another. In 70 cases of asymmetry where one axis is 90°, there are 10 cases of

$\frac{7.5}{9.0}$ (or $\frac{9.0}{7.5}$), 9 of $\frac{9.0}{6.0}$ (or $\frac{6.0}{9.0}$), 6 of $\frac{11.0}{9.0}$ (or $\frac{9.0}{11.0}$), 6 of $\frac{9.0}{10.5}$ (or $\frac{10.5}{9.0}$), 6 of $\frac{7.0}{9.0}$, 5 of $\frac{6.5}{9.0}$, the rest being well scattered in groups of one, two or three of a kind. The entire remainder of asymmetrical cases will not as well submit to any law, order or grouping that I am able to discover. The only approximation to such a law consists in the fact that if but one axis can be brought into coincidence with either major pole, the fellow axis is decidedly repelled away from it. In the 70 cases of asymmetry where one axis was 90° , the other was within 5° of the same in only two cases. Possibly personal negligence may in part account for this. When one axis is within 5° or 10° of one of the major poles, we are very prone to call it 90° or 180° . Within the past year I have by experience learned the importance of scrupulous exactness in this respect, and have devised a mechanical aid helping to detect these slight differences with care and certainty. Bearing still farther upon the question, I add that in 36 cases of sundry asymmetrical hyperopic astigmatism, neither axis being at 90° or 180° , I have found that 11 cases were but 5° out of symmetry, 13 but 10° out, 10, 15° out, etc. It remains an open question whether this striking difference from the cases above alluded to, where one axis was 90° or 180° , is due to my greater care, and unconscious freedom from a prepossession, in accurately locating the *unusual* axis, or to some hidden and different law. I may also add that in the 70 and 25 cases where one axis was at 90° or 180° , there is a decided and clearly marked *disinclination* of the fellow axes to cluster about or tend toward either major pole. The hyperopic axes fly from the 90° pole a little less decidedly than the myopic axes fly from the 180° pole. This would clearly argue against the personal equation or negligence theory. I should also say that the cases of symmetrical axes other than those of 90° or 180° likewise show no well-marked tendency to fall into groups or suggest any governing law.

Before leaving the subject, I wish to ask my colleagues if they have found any undoubted instances of a change in the axis of astigmatism caused by the use of the mydriatic. I have had several such cases, the patient, after the return of the accommodation, emphatically refusing the axis as clearly demanded under the mydriatic. My two most troublesome cases contradicted each other as to whether the mydriatic or non-mydriatic axis were the better. Both were cases of unsymmetrical axes, and of compound hyperopic astigmatism. One, under the drug, demanded the axis (0.37 D.) at 105° (the fellow being at 90°), and with functional accommodation would have it at 60° . I gave it at 60° , but in two months grievous pain in the eye, and chorea of the side of the face, forced me to return to the mydriatic axis, with sudden cessation of the ocular pain and

facial spasm. The other case, under the mydriatic, demanded the axis (1.50 D.) at 150° , the fellow being at 180° . This I ordered, but found soon afterward that axis 105° was desired by the functional accommodation, and this has now been worn for a year or more with perfect satisfaction. The fact has led me to scrutinize most carefully those cases in which correction of the ametropia does not relieve the symptoms. It is also pertinent to inquire if in some cases, soon after applying the glasses, the relief at first experienced, but soon ceasing, may not be due to a refractive change following and a direct reaction of the eye, its innervation, etc., to the glasses themselves.

The records of insufficiency here grouped together are based solely upon the 20-foot tests.

According to my table, 89 per cent. of all esophorias were connected with hyperopia of some kind, but that 77 per cent. of all esophorias are likewise connected with hyperopia, is noteworthy. In myopia the percentage of esophoria and exophoria is the same, and the esophoria of hyperopia is but little more than twice as high as the exophoria. It seems to me we are far from a satisfactory theory of the etiology of these conditions. Clinically I have been struck by the fact that very often a high degree of exophoria, and even somewhat often of esophoria, may be ignored without any resultant symptoms, local or

reflex. I have also found that the symptoms frequently bear no sort of relation to the degree or kind of heteropia. As regards treatment, the rule I have come to follow is to correct by prisms the internal insufficiency when above one degree and certain that it is permanent, particularly if the patient be a hard-worker at near-range. When the interni are as weak as 12° I advise tenotomy. In external insufficiency, I am greatly inclined to trust the ametropic correction alone, and certainly if no pronounced reflex symptoms exist. Experience has constantly shown me this is a good rule to follow. I remember many cases, but especially one, a woman of 30 who had never worn glasses and who usually had a positive squint of the left eye. For two years the eye keeps straight when the non-prismatic spectacles are worn, and without any reflex symptoms.

Remove the glasses and the eye rolls inward at once. She had a high degree of compound hyperopic astigmatism, the left eye requiring a cylinder 2.25 D. stronger than its fellow.

I have had a number of patients in whom, at the first examination, there was a demonstrated inefficiency of a few degrees, but who within a short time after wearing ametropic and prismatic correction were found to have a progressive weakness of the muscle. The symptoms demand attention: with increase of the prisms temporary relief is obtained, but in a month or several still greater increase of the prism is demanded. It looks to the patient as if the spectacles were making matters worse. One case ran from 6° to 16° within a year. I cut the tendon

and reduced the muscular balance to equilibrium, and am now wondering if the road is to be again traveled all over. What is taking place in these muscles? To say "spasm" seems like a *confessio ignorantie*. I always feel like exclaiming, "Bosh!" whenever spasm of any ocular muscle is mentioned.

During the time covered by these statistics I have had 8 cases of convergent and 2 of divergent strabismus, not included in the tables.

Turning to hyperphoria, I have had 20 cases: 8 of 1° , 4 of 2° , 3 of 4° , 1 of 6° , 1 of 7° , and 1 of 8° . Among these was one case of right monolateral partial ptosis in which persistent and powerful effort to raise the upper lid had wrinkled and arched the brow and forehead to a remarkable degree. The head was canted to one side and backward, and the inferior rectus of the eye had naturally become over strong. Correcting lenses, 1.50 D. cylinder with a base of prism in the right, not only relieved the distress, but has quite cured the ptosis, which, therefore, seems to have been of a reflex nature. The changed appearance of the man and his power to raise the lid is a great cause of congratulation by all his friends. I have usually corrected hyperphoria with prisms and with success. The case with 8° is an anomalous one. She has never had any severe reflex symptoms either before or since getting glasses. She had a high compound myopic astigmatism, with amblyopia, and with 4° of esophoria. With the visual axis horizontal there was diplopia corrected by a prism 6° or 8° base down in the left. But upon looking downward the diplopia disappeared, without the prism, or was reproduced by it. There was no history of traumatism. Six months after correcting her ametropia and esophoria, the hyperphoria, without correction, had reduced itself to 3° , and no reflex symptoms exist. The case I have classed as 7° ranged from 6° to 10° on different days, but was usually about 7° . This prism, while correcting the hyperphoria, with the axis of vision horizontal, and accurately facing the object, at once produced diplopia and distress with movements of the eyes, or in walking and looking about. The patient's health was so profoundly bad that I did nothing for the hyperphoria. She was a presbyope, 1.25 D., with a very small degree of myopia. In the past five months she is, under general treatment, improving rapidly in general health, and the ocular symptoms are disappearing. The patient with 6° of hyperphoria could wear for permanent use only a 4° prism, though the test clearly showed 6° . With the 4° prism he has perfect relief and satisfaction. The cases with 4° or less wear the prismatic correction with entire satisfaction.

Speaking generally, then, my experience leads me to correct all hyperphorias of 4° or less, and

most esophorias of more than 1° with prisms; to ignore exophoria until (very rarely) forced to consider it, after the patient has worn the ametropic correction for a considerable time; to perform tenotomy in decided strabismus, and then only after having worn ametropic correction for a time, and if possible with atropine in the non-squinting eye; to perform tenotomy in insufficiency, only when of 12° or over, and when accompanied by decided reflex symptoms. I have never had a case of imbalance of the muscles without an ametropia demanding correction. It is only in such a mythical case that I might perhaps be prevailed upon to consider the remote possible advisability of beginning to think of commencing the study of graduated tenotomy!

Forty-four of my cases, 3 per cent. of all, have had the same refraction error in both eyes. As to anisometropia, I have never found a difference between the two eyes so great that the proper refraction of each eye was not borne in combined action. The greatest differences I have found were from $\frac{1}{2}$ D. to 9 D. in sphericals, and $\frac{1}{2}$ D. to 6.50 D. in cylinders.

One of the highest hyperopic errors with retained acuity was + sph. 6.00 D. \odot + cyl. 4.00 D. I think the highest simple hyperopic astigmatism was, R., + cyl. 6.00 D. ax. 95° , L., + cyl. 4.50 D. ax. 85° . To this a presbyopic correction of 3.00 D. was added in improved bifocal lenses, the result being all that could be desired. I have never prescribed a myopic lens greater than 15.00 D., though I have had patients whose absolute myopia was greater. The case of double hyperopic astigmatism of 10.00 D. was certainly as high as that, though there was great amblyopia. Besides the frightful astigmatism, he had 5.00 D. of hyperopia. He was, of course, unable to read, and was quite dull of intellect. He was a sailor, and not allowed to wear glasses. One wonders how he could have done his work at all. As an instance of complicated defect, a physician and friend of mine is now wearing with great satisfaction:

O.D., — sph. 7.00 D. \odot — cyl. 1.00 D. ax. 45° ; O.S., — sph. 7.75 D. \odot — cyl. 1.00 D. ax. 135° ; prism 5° each eye, base in; prism 2° left, base up; prism 2° right, base down.

A word as to full correction. The advocates of this theory say we must aim to put the eye in an emmetropic condition; this is the ideal we seek to bring about or approximate. I deny the major premise *in toto*. The *wherefore* is logical if the *whereas* be allowed. I cannot allow it; and for the following reasons:

1. The *history* of the pair of eyes we are prescribing for is often, and generally, one of abnormal use or abuse long continued. The eye, from its very history, is in an abnormal condition, and cannot be proceeded with as if normally or physiologically reacting.

2. Long excess, deficiency or abnormalism of function has begotten organic changes in the eye and its innervation mechanism. In hyperopia the ciliary muscle is abnormally developed or hypertrophied, in myopia correspondingly weakened and undeveloped, in astigmatism unphysiologically developed. These organic and functional changes cannot be neutralized quickly, and will continue to mar the results of all cast-iron rules, and for a time dependent upon the length of evolution of the defect, the peculiarities of the reaction, the vital forces, the temperament, etc.

3. The work these eyes has to do is so far from ideal, so variant and abnormal, that abstract rules will not apply. Every case is a law unto itself. Civilization crushes ocular ideals as brutally and ruthlessly as psychical ones. Sewing girls, bookkeepers, literary people, etc., who must work at near range from twelve to sixteen hours a day, cannot have much receptiveness for ideals and abstract rules.

Many other reasons conspire to lead me to lend no ear to such advice. Sometimes I over-correct hyperopia; sometimes aim at artificial emmetropia; usually I under-correct all defects except astigmatism. I believe the bitterest of errors is to fully correct myopia. I might do it in a farmer, but in an urban liver, never. So long as one does it, I believe many of his patients will be the worse for the service, and finally drift into other hands. Nearly all patients I have had who have previously been much under the care of others, have been examples of full correction. Selfishly, it is a good plan for us to advise others. It is like virtue, we all believe in it—for others! In myopia it (over-correction, not virtue!) puts the weakened ciliary muscle to a strain the equivalent of an irritating hyperopia of a degree corresponding to the size of the error, the length of its continuance, the reacting quality of the organism and the amount of near work to be done. In hyperopia, the hypertrophied ciliary muscle will refuse inaction, or even a partial deprivation of its accustomed work, for months, and if of long evolution, for years. In astigmatism, the reaction comes very promptly, owing to its predominant nervous or functional nature, and I find that full correction is usually borne satisfactorily, though exceptions occur even here.

Instead of aiming at an ideal of emmetropia, I find I am commonly aiming at an ideal of slight myopia, varying in degree from 0.37 to 2 D. in myopia, and from 0.12 to 0.75 D. in hyperopia. In a myope this can be instituted at once, but in a hyperope never at once (unless it be for near work), but often in the course of time, or by means of a second pair of lenses for near work, though presbyopia proper is a long way off.

The abridged records of a few peculiar or instructive cases may not be uninteresting to refractionists:

1. Miss S., aged 54, an intelligent city lady, has never worn glasses, and *has never had a headache*. She was found to require the following correction:

O.D., + sph. 0.62 D. \odot + cyl. 2.75 D. ax. 60°; O.S., + sph. 0.62 D. \odot + cyl. 3.25 D. ax. 120°. Esophoria 1°, and presbyopia.

2. A child of 7, for the past 3½ years has had "spasms," the number averaging about fifteen a week. Has also screaming or crying spells lasting sometimes for one or two days. Would not permit examination of the eyes. With paralysis of the accommodation by atropine the spasms have ceased for 2½ months, except three attacks, two of which followed neglect of the drops in the eyes.

3. Miss K., aged 30; headaches at vertex all life; growing worse of late; sick at stomach for 24 hours after riding in cars. A life of misery, fainting fits, subjective visions, nightmare, weariness of life, and latterly symptoms of mental disorder. Refraction:

O. D. + sph. 2.00 D. \odot + cyl. 1.50 D. ax. 80°. O. S. + sph. 3.25 D. \odot + cyl. 1.25 D. ax. 115°. No heterophoria.

The distressing symptoms disappeared almost entirely and at once upon getting spectacles, and for the past year she continues a healthy, happy grateful woman.

4. F. M., prior to a severe attack of monocular herpes zoster ophthalmicus was nearly emmetropic. After recovery from the inflammation the affected eye required—sph. 1.25 D., \odot + cyl. 3.75 D. ax. 180°. The other eye remains unchanged and perfect acuity exists in both.

5. Professor J., requires for one eye—cyl. 4.50 D. ax. 175° \odot + cyl. 4.50 D. ax. 32°, with which he has perfect acuity the fellow-eye taking—sph. 2.25 D. \odot — cyl. 2.75 D. ax. 60°.

6. Miss McC., has had intense frontal and then occipital headaches the past four years, with distressing sleepiness most all the time, and with great anorexia. There was immediate relief of all symptoms by:

O. D., cyl. 2.75 D., ax. 150° \odot + cyl. 1.00 D. ax. 80°. O. S., cyl. 2.75 D. ax. 20°, \odot + cyl. 1.00 D. ax. 105°.

7. Mr. T., had headaches at base of brain and sick-headaches for 45 years. Has taken a "cartload of medicine;" has been cupped and leeches and "electric-battered" all his life, his neck being a mass of scars. No physician ever said "eyes" to him. He has only a low degree of compound hyperopic astigmatism, but as usual in such cases, at unsymmetrical axis. Correction of this and presbyopia, with unexpected quickness stopped his sufferings within a month.

8. Mrs. M., aged 26, had headache for 11 years, [frontal for 9, occipital for past 2 years]. At the rhythmic crisis of headache there is great numbness of the left side of the face, tongue, arm and

trunk, the anæsthesia preceded by blindness of the left eye, things appearing to dance. Pain in the left eye then supervenes, and vomiting follows. The anæsthesia lasts about ten minutes. The attacks occurred about once a month but not connected with menstruation. After correcting a slight hyperopic astigmatism at unsymmetrical axis the attacks were at once transferred to the right side of the body, changed in character, lessened in violence and have now about entirely subsided.

9. Mr. P., has for 18 years had constant severe "colds" the whole winter long. The coryza was vaguely connected with ocular irritation, lachrymation, etc. He has never worn glasses until last summer. He has a high degree of compound myopic astigmatism at unsymmetrical axis and six degrees of esophoria. There is no doubt in his mind as to the influence of his spectacles in making him entirely free from any cold the past winter.

10. An obstinate case of vernal conjunctivitis or Frühlingskatarrh, disappeared at once with correction of the ametropia.

11. Mrs. O'C., aged 32, looking as if 50, has had brutal frontal headaches for 17 years. The back part of the head is tender to the touch. Often has "blind-spells," and an abnormal appetite not satisfied by food. Forehead and eyebrows burn and as she avers, *bleed!* Says the bleeding is not from scratching or injury. Requires:

R. —sph. 9.00 D., \odot — cyl. 3.00 D., ax. 135°. L. —sph. 7.00 D., \odot — cyl. 2.00 D. ax. 75°. Has been wearing simple spherical lenses alike in both eyes from a prominent hospital.

12. R. + cyl. 4.50 D. ax. 90° \odot — cyl. 1.25 D. ax. 180°. L. + cyl. 3.50 D. ax. 90° \odot — cyl. 3.00 D. ax. 175°. The last cylinder put at 180° could not be worn.

13. A prominent oculist of a distant city prescribed without a mydriatic:

O. D. + cyl. 0.25 D. ax. 90°. O. S. + cyl. 1.35 D. ax. 90° \odot — cyl. 2.00 D. ax. 180°. By the aid of a mydriatic I find the true refraction: O. D. + sph. 1.00 D. O. S. + cyl. 2.25 D. ax. 105° \odot — cyl. 2.00 D. ax. 15°. The headache continued with the former glasses, stopped with the latter.

14. Mr. W., wearing for high myopia, a full, or an over-correction, for constant and much near use, with severe reflex symptoms ocular and systemic. I reduced the correction from 6.75 D. to 4.50 D., impairing, of course, the distant vision immensely. Immediate cessation of the symptoms followed and in two months a recovery of the normal acuteness. The old glasses cannot now be worn five minutes.

15. W. K., dyspepsia and diffuse headache for 4 years. Sick-headache, vomiting, etc., two and three times a week. Often faints in street. Past

three months headache only at vertex. Weight reduced from 194 to 140 lbs. Has consulted the best and many physicians. Has taken every drug, and done everything could be thought of. Has a defect, the most certain to work mischief of any—a typical health-wrecker:

O. D. + sph. 0.62 D., \odot + cyl. 0.62 D. ax. 180° O. S. + sph. 1.00 D. \odot + cyl. 0.37 D. ax. 45°

16. J. Y., had for 10 years had 40 to 50 attacks a day of great dizziness. Had always to ride with closed eyes, as walking a short distance, looking upward, or downward, etc., brought on an attack. Had typical agoraphobia. Cured entirely for past year by:

R. — sph. 0.75 D \odot — cyl. 1.00 D. ax. 90° .
L. — cyl. 3.00 D. ax. 30° \odot + cyl. 3.50 D. ax. 120° .

The last case but one leads me to a word as to the sort of ocular defect that is most injurious to the nervous system. The least harmful is simple myopia, so long as only of a moderate degree and without great anisometropia. I have never had such a case with any reflex symptoms. Simple hyperopia if nearly alike in both eyes will often set up no irritation in the non-sensitive and out-of-door living, but may bring trouble to the over-worked and nervous type. Anisometropia will produce disorder unless one eye be discarded. I would place simple and compound symmetrical myopic astigmatism next in the hierarchy, and then the same defect in hyperopia. High degrees of symmetrical astigmatism are often free from very bad results, and they are not productive of amblyopia. Compound hyperopic astigmatism if nearly alike in the two eyes, and especially if of high degree and symmetrical, will sometimes be borne unexpectedly well; add anisometropia and suffering is almost certain. But the very acme of torment is from a medium low degree of compound hyperopic or myopic astigmatism, each differing in quantity in the two eyes, with unsymmetrical axes and with preserved desire or ability of binocular vision. There is no nervous system can resist ruin under such circumstances. Asymmetry of axes, anisometropia and preserved desire for binocular vision is a diabolic combination that has wrecked many a life.

I have found it an anomalous fact, one usually not conforming to physiological laws, that, with ocular irritation, the reflex does not as a rule return to the eyes but is commonly inhibited, resulting in headache and cerebral abnormalism, or is derouted, resulting in reflex neuroses. I have elsewhere tried to explain this fact.¹ Classing together all the reflexes that may be called ocular in result, that do return physiologically to the eye, I find the following: (See Table 9.)

There is one symptom and consequence of eye-

TABLE IX.—EYE-STRAIN, WITH OCULAR REFLEXES.

Symptom.	Cases.	Per Cent. of all Refrac. Cases.

	245	17.0

strain that I have omitted to mention because it required especial explanation: I have named it ametropic choroido-retinitis. I have urged it upon the notice of the profession because I grow more assured that however much subsequent observation by others may modify the clinical and etiological features I have pointed out, there will still remain a great significance and an inexpugnable residuum of truth in my contention. Stated in general terms I find that the cause of eye-strain, *i.e.*, abnormalism of the image-focalization and position, is also the cause of macular abnormality or disease. When the untrue focalization or position is within the strained power of the compensatory mechanism, to neutralize the fact of eye-strain with its infinite variety of symptoms is patently present and the all-important fact. When the compensatory apparatus is unable to neutralize completely or habitually, there will in time, and in the great majority of cases, arise an unnatural condition of the macular or fovea, evidenced objectively by local abnormalism of pigmentation or coloring, and subjectively by subnormal acuity in advanced cases or by disproportionately lessened response to reduce illumination. The ultimate condition of advanced cases is commonly called central choroiditis. The phenomena has nothing in common with "drag," "conns," or other nerve-head, or mechanical changes in stretching globes—except that a common cause often precedes both. It is difficult to examine the macula, and the pigmentary changes are usually so slight that these are naturally overlooked and hence an excusable though sometimes amusing skepticism. The symptom of disproportionately lessened retinal reaction to lessened illumination seems to me of great value and significance. It is essentially one with the commonest symptom of all eye-strain patients—sleepiness in near-work by artificial light. The transmutation of an imperfect image or æther-waves by the retina, into a series of neural impulses, is a severe labor, and produces abnormalism of the peripheral or retinal end-organ at the point of greatest impact and labor. Unphysiological stimulus always necessitates abnormal changes in the recipient mechanism. Hence the retinal injury. The brain has a still severer labor to manufacture out of the in-

¹ "The Influence of Sexualism in Reflex Ocular Neuroses," Med. and Sur. Rep., March 9, 1889.

sufficient and non-representative retinal stimuli an effective sensation, and to form judgments that shall complete and compensate the misrepresenting image.

Severe labor tires, and the exhaustion of the cerebral mechanism is evidenced by sleepiness. I think 90 per cent. of the eye-strain patients will have the symptoms and wonder how you know about it.

On account of the duplication of symptoms and the indefiniteness both of diagnosis and result that necessarily attends such conditions, it will be understood that the figures of the table of reflex ocular neuroses can in some ways and parts have only a low relative value. But something is gained by grouping them together. Many of the symptoms were probably of extra-ocular origin. All that is implied in the grouping is that the symptoms were often, if not in the majority of cases, of ocular origin. Different classes vary in the certainty with which one may say that they *did* so arise, and many require time to explain my reasons for the ascription. Some are directly, others only secondarily due to the ocular irritation.

Total	533	100.	58.0

The only overstatement is in the duplication of symptoms arising from the fact that often these patients have several of the symptoms. This

overstatement, however, will but partially neutralize the understatement of failing, in the hurry of practice, to elicit or get down on paper the details of symptoms. I have had no Hahnemannian symptom, microscope or kaleidoscope, and I hope I value truth more than a specialist's special pleading.

As to headache, its significance is not recognized because its death-bringing power is so slowly operative, and because it finally employs other diseases to do its work. But it cannot be forgotten that if the brain is the highest seat and center of vital and regulative life, its paining must mean destructive or harmful activity for all the vital powers. Careful clinicians will assent to this. Furthermore, it must arouse the most sluggish, if it be also true that certainly three-fourths of all headache are due to eye-strain. If you think 90 per cent. I shall not disagree. I am quite sure that over 75 per cent. of all my patients have had headache, though I find but 58 per cent. reported in my table. What proportion have been cured, or so greatly benefited as to be called a cure? Certainly 95 per cent. or more. As to sick headache, I believe it due to eye-strain in 90 or 95 per cent. of cases. Compare the opinion of that veteran neurologist, Seguin.² Sometimes it is not quickly, sometimes not even at all curable after 30 or 40 years of habit and disordered function of the nervous system. Habit becomes structure in time. Function makes its tools and we call them organs. Swim long enough with your hand and you will surely be web-fingered by and by. But sometimes the system resists these changes and preserves the ability to throw off long habit very quickly. Let me cite the case of my friend, Dr. Larcier, of Bethlehem, Pa., aged 32. He had had sick headaches twice a week for over 20 years, each attack culminating in violent emesis, exhaustion and sleep, the whole attack lasting about 24 hours. Seven months ago I prescribed for him an one-half dioptric cylinder in the right eye and an one-fourth in the left, both at axes 90°. Since then he has had three attacks, twice when he broke and was without his spectacles, and once from loss of sleep and over-eating. There is but one thing more strange than the fact, and that is incredulity as to all such facts. I wish to add that Dr. L. had also 5° of external insufficiency, which left uncorrected has fallen to 2°, where I hope it will remain.

By mental symptoms I mean not the indefinite and vague ones often affecting the disposition or character, as any worry or pain will do, but cases in which after many years or a lifetime of suffering caused by eye-strain, the mental moorings showed positive evidences of giving away, and melancholia, loss of memory, illogical acts, etc., became painfully apparent.

²Keating's Encyclopedia of the Diseases of Children.

I have only lately realized the direct agency of eye-strain in causing night-terrors, insomnia, or non-restful sleep, especially in children forced by ambition, parental pride or an outrageous school system. The profound disturbance of the central nervous system cannot be followed by restful sleep. The injury to its own mechanism must first be healed and equilibrium established there before the normal work, the repair and restoration of the waste and depletion of the peripheral organs can proceed. It is a sad error on the part of those who treat children's diseases to ignore this tremendous factor. The few cases I report are, I am sure, but a fraction of those from whom I failed to elicit the symptom. And how few such little patients reach the oculist in time! Almost without exception parents tell me the nightmare, movements and crying-out in the night soon disappeared after wearing the spectacles. To the same general cause I believe certain rare cases of nocturnal incontinence of urine may be traced. Two cases stopped after the ocular headaches were cured.

As to chorea, I know the smile of incredulity of the neurologists. The smile—not of disbelief—will be in their patients' faces when the prejudice melts away. All that I contend for is that in some cases eye-strain may be a cause, may be the cause. I agree that in the majority of cases it is not the cause. Hardly one of my patients was not better, and several, the worst ones, were cured. When the lenses are broken, the frames bent, or the refraction itself with growth has changed, the choreic movements speedily recommence. Sometimes, when only a coöperating cause, each of the dual or triple causes must be separately dealt with to effect a cure; but the ocular examination under a mydriatic must not be omitted.

I have had several cases of what I have called chorea of the heart, violent palpitation, caused very certainly by eye-strain, and cured by its relief.

I know nothing of epilepsy due to eye strain, except in one instance, that I believe will soon prove itself to be such, sufficient time not yet having elapsed to be dogmatic about it. The case under observation has been growing worse, all treatment utterly ineffective, the etiology wholly mysterious. If the man reads a little while there is violently spasmodic closure of the right eyelids, intense sleepiness, headache, etc. A more fiendish refraction error could hardly be invented:

R. + sph. 0.62 D. \odot cyl. 2.50 D., ax. 175° .

L. + sph. 0.25 D. \odot cyl. 1.00 D., ax. 75° .

Extreme hyperæsthesia, exaggerated "nervousness," is a common and clearly-marked symptom of eye-strain. The patient, usually a girl or young woman, is restless, excitable, hysterical, easily frightened, has absurd "crying-

fits," outbursts of violent anger, etc. With spectacles the change from all this is remarkable, and remarked by parents.

I have had a number of patients whose trembling and loss of steady control of the hands or head seemed connected with the nervous storm aroused by ocular work without proper glasses. During the ocular headache the trembling was far worse. "Blind spells" sometimes supervene in the crises, or just preceding them, of ophthalmic migraine and sick headache, and in these crises three patients have complained of great loss of feeling, a benumbing of the hands, arms, lips, etc.

Most of the menstrual abnormalities I have certainly traced to eye-strain are delayed institution of the menses, and amenorrhœa. In two cases the mothers of girls of 16 or 17 years, reported that the long-delayed flow came with a gush within a week or two after relief of eye-strain and its resultant headache.

One young man stuck to it that certain of his teeth always ached whenever he read a long time. I have reported a noteworthy case of stuttering and one of aphonia due to ocular irritation.

Some of the most curious cases I have had were instances of localized and persistent pain,—*e.g.*, a cold tender spot above the right ear, the size of a silver dollar; a swollen patch in front of one ear; a pain continuous for $2\frac{1}{2}$ years in the back of the neck, made worse by reading, and disappearing in 24 hours after getting glasses; a severe pain in the back between the shoulders persisting for many years all the time. It disappeared within a day or two after proper spectacles were worn, was absent for three months, reappeared in 24 hours after glasses were broken, continued for the four days during which the lenses were being reground, and again vanished in a day when the repairing was complete. Has not returned during the past year.

TABLE XII.—DIGESTIVE AND ASSIMILATIVE DISORDERS.

Variety.	Cases.	Per Cent. of all Reflex N.	Per Cent. of Refrac. Cases.
Anorexia and Fickle Appetite . . .	134	10.	9.3
Anorexia, alternating With Abnormal Appetite	8	1.	...
Inordinate Appetite always . . .	1
Constipation	28	2.	2.
Dyspepsia	51	4.	3.5
Nausea and Eructs—not Sick-headache	3 ^c	3.	2.6
Car-sickness	17	2.	1.2
	277	22.	19.3

For a long time I have been begging my friends, the general practitioners, to heed the fact that digestion and assimilation may be directly and profoundly disordered by eye-strain. Nothing seems to me more true in medical science than this. I by no means claim that all the cases of my table were the sole result of eye-strain. I have never

had a patient who complained of car-sickness who [if returning to report] was not free from it after wearing glasses. Besides these and sick-headache cases the cases of nausea and vomiting connected with use of the eyes and relieved by "artificial emmetropia" are quite numerous. But by far the most important disorder of the digestive system due to eye-strain, is anorexia—sometimes alternating with excessive appetite. These case of anæmia and malnutrition are almost always young girls or young women, and my records show almost without exception that after relief of eye-strain, the appetite becomes more regular and strong, there is a gain in flesh, health, spirits etc. I am thoroughly convinced that typical cases of anæmia have finally drifted into hysteria and chronic invalidism, when, if taken early, a simple pair of proper spectacles would have brought and preserved health. It is thus, by reducing the general vitality or resisting power of the nervous and assimilative systems that to eye-strain may be indirectly due any type of general organic disease of disastrous consequence or fatal issue. The work of the naturally hyperopic eye, set to unused and impossible tasks by civilization, is directly or indirectly a prolific source of indescribable mischief. If the theory of evolution be true it follows that an organ slowly evolved during millions of years for a special task, distant vision, cannot, in a century or less, be made to different work without disorder and trouble. With one little artificial help, the whole disaster and trouble may be forefended. Just how these strange reflexes are brought about no one would be bumptious enough to pretend to say, since no one can tell why pain follows a pin-prick, or why a nutastatic orchitis may follow parotiditis. These symptoms and results of eye-strain are infinitely diverse, apparently illogical, wonderfully concealed and subtle. Every case is a rule unto itself, so that one can give few general laws to one learning the art. Refraction is a science and an art in intimate union and requires as much patience, delicacy of perception, fineness of judgment and discrimination as any scientific work in the world. In relation to it there are vast fields of inquiry the wisest have hardly begun to explore. The amount of human misery caused by those ocular defects is appalling, and if the prevention and relief of that misery be the motive of scientific medicine, no branch is more important or demands higher powers of mind than that of ophthalmology—and nine-tenths of modern ophthalmic practice consists of refraction!

DISCUSSION OF DR. GOULD'S PAPER.

DR. H. MOULTON asked Dr. Gould if in any of his cases he had seen the axis change after passing from under atropia. Said he had met

such a case, the axis under atropia being 90° and without 110° .

DR. SAVAGE said there could be but two causes for the best meridian under and after atropia. He attributes the difference to deviation of the vertical axes of the eyes caused by the oblique muscles.

DR. G. W. ALDYN said if spasm of accommodation is to be regarded as a fiction, as implied by Dr. Gould, he desired him to explain how a change so great as the following could be accounted for:

O. D. + 2. \bigcirc — 3 cyl. horizontal = $\frac{20}{20}$,
under atropine. O. D. + 5. \bigcirc + 3 cyl. vertical = $\frac{20}{20}$.

PAPILLOMA OF THE CORNEA, WITH REPORT OF A CASE.

Read in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY S. C. AYRES, M.D.,
OF CINCINNATI, O.

It sounds somewhat contradictory to say that a papilloma can develop from a surface which is not naturally supplied with papillæ. At first it would seem impossible, but the vagaries of neoplasms are numerous, and this seems to be one of them.

Von Ziemssen, in *Ziemssen's Archives*, Vol. vii, in speaking of papillæ of the larynx, says:

"The development of papillary growths occurs not only off the mucous surface originally provided with papillæ, but, as is especially shown by Virchow (*Krankhafte Geschwulste*, 1, pp. 334 and following), also in regions where papillary structure of the mucous membrane is entirely lacking. The first step is the proliferation of the superficial connective tissue, the development of a little amorphous granular or homogeneous nodule, in which cells are not to be recognized until later. As the cells multiply, they gradually grow and put forth buds, just as is done by the preëxisting papillæ. The capillary loops of the papillæ are large; the surface of the neoplasm is covered with a thick layer of epithelial cells.

"The size and form of papillary tumors are very various. At first they represent little buttons or pegs; afterwards warty formations, as those representing a cock's comb; in case of luxuriant development, high growth similar to a berry, grape or cauliflower in form, which may partly or entirely fill the upper and middle, more rarely the laryngeal cavity."

Cornil and Ranvier say in relation to the development of papillomata, "that mucous papillomata generally spring from the villi or papillæ of the mucous membrane, but they form [where there are no papillæ, for example, in the ventricles of the larynx." The minute phenomena of these hypertrophies and new formations have not

yet been followed very closely, but the analogy of their structure with that of inflammatory granulations, supports the supposition that their mode of formation is similar. They say further as to location, that we find papillomata seated upon nearly all parts of the cutaneous and mucous surface.

Dr. Sajou, in his work on Diseases of the Nose and Throat, says that "papillomata are wart-like growths occasionally found in the nasal cavities of young subjects. They are most frequently attached to the septum and to the inferior turbinate body. They vary in size from that of a lentil to that of a small chestnut, and present a very light brownish color, with an irregular corrugated surface."

In relation to papillomata of the larynx he says: "This class of growth does not present a characteristic appearance which enables a positive diagnosis to be made; they, however, possess certain properties in common which render an approximate recognition of the nature possible."

They often present small round projections which cause them to be termed raspberry, mulberry, cauliflower, etc., because of their resemblance to them; they are usually located at the anterior portion of the larynx, and on the vocal bands near the anterior insertion.

Mackenzie, in his work on the Diseases of the Nose and Throat, says that papillomata are by far the most frequent of all benign growths of the larynx. He says also that papillomata are found in the nose, and are more common than is generally supposed.

Throughout the ophthalmic literature I see numerous reports of cancrroid of the cornea. In the seventh volume of Graefe's Archives is a report by von Graefe of two cases of cancrroid of the cornea which he scraped off, and which, from the description, resembled my case in its early stages, but it was composed of epithelial cells with a very little connective tissue. In the fourteenth volume of the same, Dr. Knapp reported two cases of cancrroid of the cornea and limbus conjunctiva, but nothing is said of the microscopic appearance of the growths. Cases defined positively as papilloma are not very numerous in the literature at my command.

In the *Lyons Medical* for 1879, M. Gayet reports a case of papilloma of the cornea. It was seated on the left cornea of a man 67 years of age. The disease was two years in reaching its present size and had never caused much pain. It occupied four-fifths of the cornea and left only a small portion of the periphery free, vision being only lateral and reduced to $\frac{1}{8}$. The tumor, flat, and compressed by the action of the lids, was of a rose gray tint, and presented a characteristic appearance. Examined histologically it was demonstrated to be a papilloma to the exclusion of sarcoma and epithelioma. It was treated by a

powder of alum dusted on its surface with a hair pencil and the result was surprising. It disappeared in the course of two months and there was a *restitutio ad integrum* of the cornea, and vision was increased to one-fourth. Berry, in his excellent work on the eye, in speaking of tumors of the conjunctiva, says, that of the non-malignant forms, perhaps the most common are papillomata. They usually occur as multiple excrescences from the conjunctiva at the inner angle of the eye in the region of the caruncle, but are found at the same time springing from the palpebral conjunctiva. These surfaces are often uneven and crenated, but may also be smooth.

Pollock in his work on Histology of the Eye, say that Sczokalsky has described a tumor arising from the limbus conjunctiva, in which the papillary processes composed of spindle shaped cells containing blood vessels, were covered with a stratified epithelial layer.

Alt examined a growth of the conjunctiva in which there were epithelial papillae, amongst, and in the cells of which lay granules of pigment.

In the Transactions of the American Ophthalmological Society for 1879, Dr. Wm. F. Morris of Philadelphia reports a case of recurrent papilloma of the corneo-scleral junction. It was in the person of a man 56 years of age. It was about half in the sclera and half on the cornea, and the tip of the growth extended about to the center of the cornea. It was first dissected off and then cauterized. It returned and in five months the operation was repeated. It was then cauterized with nitric acid, and this time it was successful, there having been no return of it since.

At the meeting of the Ophthalmological Society of the United Kingdom, December 13, 1883, Mr. Anderson Critchett and Mr. Juler exhibited a case of papilloma of the conjunctiva. It had been first noticed when the patient was nine years old and she was now fourteen.

Schiess Gemeuseus observed a case of papillary excrescence on the conjunctiva of both lids in a young man 17 years old. It had a whitish rough surface. It had existed for about six months. In the cheek of the same side there was a lupus. The papilloma was treated by scarification and the use of silver nitrate in solution and astringent applications.

In the *Recueil d'Ophth.* Jules Fontan reports a case of adeno-papilloma of the conjunctiva.

H. C. Boenning, in the *Philadelphia Medical Times*, reports a case of hairy papilloma of the conjunctiva.

Ewetzky describes a case of papilloma of the cornea and conjunctiva in the person of a woman 50 years of age. It covered the entire cornea except a part of the outer and lower quadrant. Upwards and inwards from this tumor and about 2-3 mm. distant on the conjunctiva was another similar growth.

The case which I here present was in the person of Mrs. K. G., æt. 50, a healthy, well-nourished woman, who was seen first on the 7th of May, 1889. There was a large growth on the anterior portion of the left eye, involving the entire front of the ball. It had the appearance of a cauliflower, and its edges spread out beyond its attachment to the globe. It projected 1 cm. from the sclera, and its horizontal diameter is

3½ cm., and its vertical diameter 2 cm. Her history is as follows: She says that six years ago she noticed some veins extending from the outer portion of the ball inwards towards the cornea, where there was a slight elevation on the sclera. This continued to grow and enlarge until about two years ago, at which time it was about as large as a small hazel nut. It was then removed by her physician, but it grew very rapidly, and he removed a portion of it every week or two. He kept up this method of treatment for about six months, when he discontinued it. The tumor was allowed to grow unchecked until August, 1887. At that time it had grown to the size of a large hazel nut, and protruded between the lids. It seems, however, that up to this time it had not encroached very far on the cornea, as she says she could still see very well. In August and September, 1887, it was operated on several times, a small portion being cut away each time. Since then it has been allowed to grow unchecked by any surgical interference (a period of twenty months), until it has assumed the proportions I have given above. There is no history of cancer in the family, and it has not been accompanied by any pains which might be indicative of a malignant growth. It annoys her by its immense size, and the consequent exposure of its surface to the air, as the lids do not completely cover it. I advised enucleation, as the eye was very unsightly, and there was no possibility of restoring any vision. To this she readily consented, and the globe was enucleated without much difficulty in the ordinary way. She made a rapid recovery, and since then, now two years, there has been no return of the growth. The specimen was examined for me by Dr. James M. French, who gave the following report:

The specimen from the eye of Mrs. G., which you recently gave me for examination, proves to be a papilloma. Its structure consists of exceedingly delicate papillæ, which appear to spring

from almost the entire anterior surface of the cornea. I have not yet been able to make an altogether satisfactory section of it, but I think that the growth must have originated from the conjunctiva, and that its presence upon the cornea is only an extension of the tumor upon its surface; for I cannot conceive of the possibility of a papillary growth originating from a tissue like the cornea. I cannot state positively that

the connective tissue of the central portion of the papillæ is, or is not, directly continuous with the corneal tissues, but such appears to be the case, the cornea having become vascular.

The only interesting feature, microscopically, of the tumor, aside from that to which I have just referred, is the very long, slender and delicate character of the papillæ, which appear to be primary.

I have not yet been able to find any secondary off shoots, and if any are present, they originated at, or very near to, the apices of the primary papillæ. The central fibrous framework of the papillæ is very delicate, and supports little more than a single layer of columnar epithelial cells, without a well-marked corneous layer. The tumor was, of course, benign in character.

In this case there seems to have been no doubt as to the microscopic structure of the growth, its distinctive histological characteristics being beyond doubt. I regret I am not able to present to you more confirmatory reports of parallel cases.

EXCISION OF DISEASED EYEBALL, FOLLOWED BY RELIEF OF REFLEX CEREBRAL SYMPTOMS.

Read in the Section on Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY H. MOULTON, M.D.,

OF FORT SMITH, ARK.

CONSULTING SURGEON TO THE EYE AND EAR DEPARTMENT, ST. JOHN'S HOSPITAL.

The following case seems rather unique, hence is reported:

Mr. R., æt. 40, single, and a farmer, was sent to me May 19, 1890, by Dr. Thomas, of Booneville, Ark. When 6 years old, some lye thrown into his right eye had destroyed its sight. The eye then gave no special trouble until twenty years afterwards, when it became inflamed and ruptured, discharging the lens and part of the vitreous. During the past twelve years it has

been subject to occasional attacks of pain, mild at first, but becoming more severe and of greater frequency. For a year or more the patient has suffered from almost constant frontal headache. During the past eight months, insomnia and symptoms of mental aberration were added. The mental trouble assumed the form of melancholy. The patient became suspicious of his friends, fearing bodily and other injury at their hands, and attempted on several occasions to leave his home. At the date of his appearance in my office, the right eyeball was merely a small, hard, shrunken cicatricial button, tender to the touch. V. L. E., $\frac{20}{40} + 1.20 = \frac{20}{20}$. Under cocaine, the right eye was enucleated May 20. The patient reported the first sound night's sleep for many months. He was free from headache, and felt more cheerful and better in every way. This improvement was lasting, and he became himself again, following, during the next summer and winter, his usual avocation. It seems his headache, insomnia and melancholia must have been aggravated, if not caused in a reflex way, by *cicatricial* compression of the terminals of the nerves supplying the eyeball, producing cerebral vascular disturbances. Reflexes arising in a similar way are mentioned¹ but rarely.

I have just learned that the patient's friends have some fear of a return of his melancholy. Should this eventually prove true, it yet seems, from the great improvement following the operation, that the relation of cause and effect, as above premised, must have existed.

DISCUSSION.

DR. EDWARD JACKSON said he once enucleated an eye in a patient in whom there was mental aberration, which he attributed to fear.

DR. C. A. WOOD called attention to the fact that many cases of temporary insanity are relieved by the operation, but recurrences are liable to occur. He thinks insanity may be anticipated in such cases.

DR. FROTHINGHAM said that in connection with this case reported by Dr. Moulton, he wished to mention a case in which he had removed two painful stumps of eyes from a young lady for the relief of intense headaches that seemed due to the irritation which they caused. The headache was the trouble from which the young lady sought relief, and it was permanently cured by the operation.

THE sum of \$30,000 has been collected for the establishment of a children's hospital in Louisville, Ky., in commemoration of the destructive tornado which some time ago passed over that city. This is a very literal translation of the old proverb, "It is an ill wind that blows nobody good."

TREATMENT OF IRIDO-DIALYSIS FROM CONTUSION. PARTIAL IRIDENKESIS, WITH OR WITHOUT SURTURE.

Read in the Section on Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY EUGENE SMITH, M.D.,

PROF. OF OPHTHALMOLOGY AND OTOTOLOGY DETROIT COLLEGE OF MEDICINE.

Among the anomalies of ophthalmology is the condition known as irido-dialysis from contusion. Anomalous, because, while well known to all ophthalmologists, described in all ophthalmic works of importance, and its discomforts fully recognized, no treatment is advised or even suggested.

That treatment is unimportant in the lesser degrees of the trouble, "goes without saying;" but in cases where the separation of the periphery of the iris is one-fourth of its circumference, and the accommodation normal, as occasionally happens, the dazzling and monocular diplopia is extremely annoying. This is particularly the case when the detachment is situated at the inner, the outer, or the lower periphery.

The segment of iris torn from its peripheral attachment becomes paralyzed, and later on, atrophied.

Many years ago Critchett gave us the operation of iridodesis, which Stellwag, Wecker and others have modified, and the operation which I have found so successful is a yet further modification of Critchett's, or rather, of the iridenkleisis of Stellwag, with this difference, the whole width of the iris from the pupillary border to the detached periphery is not dragged into the wound at the sclero-corneal junction.

With these few remarks I will ask your consideration of a method of treating these cases which I have employed four times in the past five years, which in each case has been successful, and which, as yet, has been followed with no untoward results.

My operation is as follows: A narrow, somewhat slanting incision is made in the cornea near the sclero-corneal junction with a broad needle or a very small keratome. Fine forceps are introduced and the iris near its detached periphery is seized and drawn into the wound. A small portion only is drawn through the wound, enough only to insure being held in position by a compress bandage till healing has taken place. In order to more thoroughly secure its maintenance in the wound a fine suture may be passed through the conjunctiva at the border of the wound and the iris stitched thereto. The suture may be removed in 48 hours. In three of my cases the operation was made as described without suture.

The fourth case was quite extensive, the rupture measuring 10 mm. long and 4 mm. wide.

¹ Internat. Encyc. Surg., Vol. v, p. 210.

In this case I made a double incision, the two incisions being about 4 mm. apart, and I drew a bit of iris into each wound. I did this because a single antero peripheral adhesion of the iris would be insufficient to cover the peripheral rupture.

The case recovered without untoward symptoms and was perfectly well 7 months later, at which time I last saw him.

Objection to the operation may be offered on the plea of possible sympathetic mischief from dragging, but as the operative procedure does not restore the ruptured nervous connection this danger is problematical, if not chimerical.

DISCUSSION.

DR. G. W. ALLYN, Pittsburgh: A man 47 years of age who had lost his right eye by a former accident came for treatment of his left and only useful eye.

A fragment of steel had struck the center of the cornea a glancing blow, cutting outward and well into sclera. Through this wound a ribbon of the iris detached from the outer third of its attachment protruded as a loop. Hoping to preserve a central pupil I carefully cut the protruding iris, leaving the ends in the wound. The eye healed in time. When ready to resume his work a glass correcting the astigmatism gave a vision of $\frac{2}{10}$.

At the end of one year I find the astigmatism less and the vision unimpaired for all of his work, parts of which are very exacting.

SECTION OF STATE MEDICINE, 1891.

Chairman, J. D. Plunkett, Nashville, Tenn.
Secretary, Benj. Lee, Philadelphia, Pa.

FIRST DAY.

The Section met at the Columbian University, Washington, D. C., at 3 P.M. There were present and registered during the session

John H. Rauch, Springfield, Ill.
N. S. Davis, Chicago, Ill.
A. N. Bell, Brooklyn, New York.
J. B. Lindsley, Tennessee.
C. G. Comegys, Cincinnati, O.
Charles McIntyre, Pennsylvania.
M. G. Motter, Lancaster, O.
G. H. Rohé, Baltimore, Md.
J. Harvey Reed, Mansfield, O.
Gustavus F. Franklin, Chillicothe, O.
D. F. Lincoln, Geneva, New York.
W. Wyman, U. S. M.-H. S.
T. A. Foster, Portland, Me.
C. W. Chancellor, Baltimore, Md.
C. A. Lindsley, New Haven, Conn.
Benj. Lee, Philadelphia, Pa.
A. L. Gihon, U. S. Navy, Brooklyn, New York.
J. T. Reeve, Appleton, Wis.
J. Bochrán, Montgomery, Ala.
C. O. Probst, Columbus, O.
J. N. McCormack, Bowling Green, Ky.
G. S. Franklin, Ohio.

J. F. Hibberd, Richmond, Ind.
J. T. Motter, Georgetown, D. C.
Charles H. Shepard, Brooklyn, New York.
B. O. Reynolds, Lake Geneva, Wis.
W. C. Briscoe, Washington, D. C.
H. F. Lyster, Detroit, Mich.
J. H. Hamilton, Richford, Vt.
D. J. Jennings, Cleveland, O.
E. A. Gibbs, Washington, D. C.
Geo. Purviance, U. S. M.-H. S.
D. Sinste.
Geo. Homan, St. Louis, Mo.
John H. Fulmer, Quakertown, Penn.
Frank Ball, Lock Haven, Penn.
A. P. Hull, Montgomery, Penn.
Geo. W. Jenkins, Kilbourne City, Wis.
Lawrence F. Flick, Philadelphia, Penn.
Robert Selden, Catskill, New York.
H. W. Thayer, Corry, Penn.
O. F. Shelden, Lyons, New York.

In the absence of the chairman, Dr. J. D. Plunkett, Dr. John H. Rauch, was, on motion of Dr. J. Berrien Lindsley, called to the chair.

The address of the chairman being necessarily passed over the report of the Committee on School Hygiene was read by Dr. D. F. Lincoln, Chairman of the Committee. Dr. Lincoln prefaced his report by the statement that it was mainly synoptical and presented only such results as all the members had been able to agree upon. Several of the members of the committee had prepared papers on the special subdivisions of the general subject which had been assigned them respectively, and were present to read them as supplementary to the report.

At the conclusion of the reading of the report, Dr. Lincoln presented a paper entitled "Remarks on the Construction of School Houses."

The report and paper were declared open for discussion.

Dr. Gihon assented to the propositions laid down by Dr. Lincoln in the main. He considered the reference of the speaker to the hygienic defects of the hall in which the meeting was in session, especially well timed. This was a building of modern construction, erected at a lavish expense for the express purpose of a class or school room, and yet as had been pointed out, its lighting was execrable, and as he had discovered during the reading of the paper its acoustic properties were still worse. With reference to the strictures passed upon natural ventilation, *i.e.*, by means of windows, he was not so thoroughly convinced. He had when in charge of a Naval School adopted the expedient of placing a four inch board under the edge of the lower sash, thus allowing an upward current of air to enter at the junction of the upper and lower sashes, and had found that ventilation could be quite satisfactorily secured in this way without creating dangerous drafts. It was objected to this that it only furnished a means for introducing fresh air and did not provide for the escape of the foul air.

Dr. R. Harvey Reed replied that actual obser-

vation of an opening created in this way, showed that there was an alternation of inward and outward currents. The air would enter for a few moments and then pass out for a similar length of time.

He considered that the foul odor noticed on entering an ill-ventilated school room was not in any sense dependent upon or to be taken as a measure of the amount of carbon dioxide in the air of the room. It depended on sulphuretted hydrogen, carburetted hydrogen and organic filth resulting from perspiration and respiration.

Dr. M. G. Motter, of Lancaster, Pa., suggested that, in the same way that ventilation could be obtained by the four inch board under the sash, it could also be obtained by having two panes of glass so adjusted on an ordinary sash that the air could pass freely in and out between them. He inquired whether inspection of schools was not a proper function of the Health Commissioner of a city.

Dr. C. A. Lindsley held that even though the air from a window raised with the four inch board entered with an upward direction, its density compelled it to fall upon the heads of those near the window before admixture with the general air of the room.

Dr. McIntire agreed with Dr. Reed that the odor of the room in no way depended upon the presence of carbon dioxide, but upon the organic impurities, and that on the other hand the amount of carbon dioxide present, could not be accepted as a test of the impurity of the air.

Dr. Lincoln remarked, in reply, that undoubtedly emanations of various kinds and of all kinds from the human body contributed to the foulness of the atmosphere of a school room, but that where carbon dioxide was found in excess, as a product of respiration, it indicated necessarily the presence of other impurities, also products of respiration and other excretory processes which are extremely difficult to detect and to determine. The value of the determination of the percentage carbon of dioxide, therefore, was that of a general indicator of impurity.

Dr. Chancellor considered it of quite as much importance to provide special means for the expulsion or exhaustion of the foul air, as for the introduction of the fresh. Two bodies cannot occupy the same space at the same time. Unless the foul air is first removed, the fresh air cannot enter. In cold weather the pure air should be introduced warm; the outer air at a freezing temperature should not be brought in.

The difficulty of obtaining a pure outer air in crowded centres of population is not sufficiently appreciated. In these days of rapid transit why should we not establish our public schools in suburban districts, where there is an abundance of pure air, and furnish proper facilities for the pupils to reach them.

Dr. Lincoln pointed out the extensive character of the work assigned the committee, stated that it did not by any means consider that it had yet accomplished this work, and in the name of the committee requested its continuance.

On motion, this request was unanimously acceded to.

The committee thereupon continues as follows, to report next year :

Committee on School Hygiene.—D. F. Lincoln, Geneva, N. Y., Chairman; Geo. H. Rohé, Baltimore, Md.; J. G. Pinkham, Lynn, Mass.; W. L. Schenck, Osage City, Kansas; R. Harvey Reed, Mansfield, Ohio.

Dr. Rauch requesting to be excused from the duties of the chair, Dr. A. H. Gihon was, on motion, called to its occupancy.

Dr. Gihon inquired whether the roll of the Committee on State Medicine had been called, and stated that it had been customary to do so. The roll was therefore called, and it was found that but five members out of forty-two (two of the committee being deceased) had registered in this Section. Further discussion of the subject was deferred until after the reading of the papers.

Dr. R. Harvey Reed of Ohio then read his paper entitled "Original Investigations on the Heating and Ventilation of School Buildings." This paper was accompanied by the exhibition of a large number of charts illustrating the following points from actual and accurate observation :

1. Date and time of day inspection.
2. Name of building and room.
3. Number of cubic feet of air in room.
4. Number of pupils present.
5. Outside temperature.
6. Temperature of room at levels of head, feet and ceiling.
7. Humidity outside.
8. Humidity in room at levels of head, feet and ceiling.
9. Kind of heating apparatus in use.
10. System of ventilation employed.
11. Number of cubic feet of fresh air supplied and of foul air discharged per hour.
12. Estimation of amount of carbon monoxide present in the air of the room.
13. Estimation of the amount of carbon dioxide present in the air of the room.
14. Consideration of the amount of organic matter present in the air of the room.
15. Bacteriological examination of the air of the room.
16. Miscellaneous remarks and suggestions.
17. Conclusions.

The paper of Dr. Geo. H. Rohé, member of the Committee on School Hygiene, was then read by the author, the title being "The School Sanitary Inspector; His Qualifications, His Duties, and His Powers."

The paper of Dr. W. L. Schenck, a member of

the same committee, on "The Personal Hygiene of School Children," was next in order. In the absence of the author, the secretary read an abstract of the paper which had been prepared by the Chairman of the Committee, Dr. D. F. Lincoln. The subjects embraced were Physical Training, Study, Time and Amount; Recess and Location, Instruction in Hygiene, by Whom and How to be Taught, and the Prevention of Contagious Diseases.

The Secretary read a telegram from Dr. Octavius A. White, who had been announced to open the discussion on this subject, stating that illness prevented his presence. Dr. Gihon therefore called upon Dr. N. S. Davis, as the oldest member of the Section, to take his place.

Dr. Davis spoke in terms of high commendation of the industry displayed in the preparation of the report and the various supplementary papers, especially the tabular work of Dr. Reed's paper.

The period of childhood was certainly that in which the greatest results could be accomplished by proper hygienic influences. Could we have such influences in active operation in school as well as at home, it is not too much to hope that nearly all of the defects which we call hereditary could be eliminated from our people in the course of a few generations. It should be the especial duty of the physicians to instruct the heads of families in which he is the medical adviser in the laws of health, especially as regards growing children.

Dr. Cochran being called upon, said that he had listened with amazement to the proposed qualifications for school inspectors. Certainly it would be a long time before it would be possible to inaugurate such a system in his part of the country. He could only express his gratification at what had already been accomplished by the gentlemen who had read the papers.

Dr. Hibberd described the condition of the country school house of his early days, in which lack of sufficient introduction of fresh air was not a noticeable feature.

Dr. Lyster, of the Michigan State Board of Health, spoke with regard to that portion of Dr. Reed's paper which referred to the Smead system approvingly. His board had been deeply interested in the study of that system in numerous educational buildings in their State. So far as it was associated with a process for dessicating fæces, they had been compelled to report adversely upon it. When disconnected with any such process, and used simply for the introduction of pure warm air and the exhaustion of impure air it certainly worked admirably.

Dr. McCormack, Secretary of the State Board of Health of Kentucky, while deeply interested in so much of the papers as he had been fortunate enough to hear, and commending their purpose, coming as he did from a Western State,

felt that the suggestions were many of them such as could only be successfully carried out in the land which we name Utopia.

He moved that the reports and papers be referred to the Association and the committee continued. It was carried.

Dr. McCormack stated that a resolution was passed in the Association at the morning's session, calling upon each Section to appoint a committee to confer with similar committees from the other Sections to consider the subject of perfecting the organization and improving the work of the Sections.

He therefore moved that the chair appoint a committee of three for this purpose.

The motion was carried and the chair appointed Drs. R. Harvey Reed, A. N. Bell and J. T. Reeve as such committee.

The Section then, on motion, adjourned to meet at the same place on Wednesday, May 6th, at 3 P. M.

SECOND DAY.

The Section convened at 3 P. M., May 6, 1891, pursuant to adjournment.

Dr. J. Berrien Lindsley of Nashville, Tenn., the oldest ex-chairman present, was, on motion, called to the chair.

Dr. N. S. Davis of Chicago, Ill., then presented his report as chairman of the Committee on "Meteorological Conditions of the Atmosphere and Their Relations to Coincident Prevalence of Disease." The report was founded on an immense number of careful meteorological observations, and sanitary and mortuary returns, showing much faithful and persevering labor. It drew attention to the apparent influence of the presence of ozone and peroxide of hydrogen in the atmosphere in diminishing the amount of albumenoid impurities. The alternate prevalence of typhoid fever and pneumonia was adduced in favor of this theory. A considerable portion of the report was devoted to the consideration of the influence of the presence of epidemic influenza, in increasing the frequency of many other diseases, such especially as pneumonia, acute bronchitis, typhoid fever and diarrhœal affections.

The report was listened to with deep interest. Discussion being called for, Dr. Flick, of Pennsylvania, considered that a serious source of error existed in all our statistics of influenza, from the fact that many cases of pneumonic complications were reported as pneumonia, which, when the symptoms were carefully sifted, could not be maintained to be so. It was a special condition peculiar to influenza, in which localized foci of inflammation were found distributed throughout the lung tissue. The same might be said of the diarrhœal complications. Strictly, all of these cases should have been returned as influenza.

Dr. Farrington, of Ireland, who was present

by invitation, drew attention to the somewhat remarkable fact, that the statistics of influenza in his country showed that this disease made its appearance with them at about the same time that the earlier cases were reported in America.

Dr. Davis was fully aware of the errors liable to creep in from false diagnosis, as referred to by Dr. Flick. These liabilities, however, existed at all times and in all places. They were not confined to times of epidemic or to certain cities. His own impression was very strong that, during the prevalence of an epidemic, and especially one of such an affection as influenza, which manifested itself in so many different ways, the danger was rather that other affections should be falsely designated as cases of the prevailing disease which was uppermost in every mind, than the reverse. The same remarkable simultaneousness of appearance observed by the gentleman from Ireland, on the two sides of the Atlantic, was observable in different sections of our own country.

In conclusion, Dr. Davis requested to be excused from a further continuance of the self-imposed labor which he undertook at the meeting at Newport, in the preparation each year of this report, feeling that his declining years and strength would not permit him to devote the necessary time and energy to it. The Secretary remarked that whatever of physical abatement of force and diminished elasticity the reader of the report might be personally conscious of, these conditions had certainly not in the slightest degree reached his mental vigor. He had been in doubt whether most to admire the great value of the report or the amount of labor which had been expended in its preparation. It was, however, due to Dr. Davis that his request should be granted, and in seconding it, he also wished to move a special vote of thanks to that gentleman for his services in connection with the Section. The motion was carried. Dr. Davis feelingly acknowledged the compliment, and proceeded to sketch briefly, for the benefit of those who should take up the work of the committee, the lines on which it had been prepared to carry on these observations. The different agencies on which he had relied for information were:

First. The United States Signal Service Observers, at such points as it had been deemed advisable to obtain data, for the meteorological observations which they are by law required to make.

Second. Other scientific observers, official or voluntary, for determinations of ozone and peroxide of hydrogen at or near the same points.

Third. Chemists, who could be relied upon for examinations of the atmosphere for organic impurities, at the same stations and

Fourth. Physicians, who were called upon to make returns of all cases of acute disease occur-

ring in their own practice, in the neighborhood of these stations.

He regretted to be compelled to say that, while the Signal Service officers were perfectly ready to give all the assistance in their power, and scientific voluntary observers were also to be depended on, and a chemist could occasionally be found who was willing to devote attention to the subject, the physicians could not be aroused to a sense of the importance of the subject, or to give the slightest assistance.

Dr. Hibberd suggested that it would facilitate the work of the Section in this respect if Dr. Davis would kindly name his own successor in the work, and a motion was passed requesting him to do so, at his convenience.

In the absence of the author, Dr. C. A. Lindsley read the paper of Dr. Joseph R. Smith, Colonel and Surgeon U. S. Army, Medical Director Department of Arizona, entitled "Sickness and Mortality in the Army of the United States."

Dr. A. N. Bell, of Brooklyn, then read his paper on "The Beneficence of Disease."

A paper on "The Sanitary and Unsanitary Relations of Underground Waters" was next read by Dr. Peter H. Bryce, of Toronto.

Dr. Lawrence F. Flick, of Philadelphia, followed with a paper on "The Duty of the Government in the Prevention of Tuberculosis."

Opportunity for the discussion of these valuable papers, which were listened to with great interest, was prevented by the fact that it was necessary to vacate the room by a certain hour.

Election of officers for the ensuing year being now in order:

Dr. Bell nominated Dr. Benjamin Lee, of Philadelphia, as Chairman.

There being no other nomination, a *viva voce* vote was taken, and Dr. Lee was announced as elected.

Dr. Hibberd nominated Dr. Lawrence Flick, of Philadelphia, as Secretary.

There being no other nomination, a *viva voce* vote was taken, and Dr. Flick was announced as elected.

On motion of Dr. Bell, it was resolved, that the Chairman and Secretary elect be a committee to nominate the members of the Committee on State Medicine, and be instructed to send the list of the names to the Secretary of the Association.

The Section then, on motion, adjourned to meet at the same place at 3 P.M., May 7, 1891.

BENJ. LEE, SEC'Y.

THIRD DAY.

The Section met, pursuant to adjournment, at 3 P.M., May 7, 1891.

Dr. J. Berrien Lindsley was called to the chair. The Secretary announced that he had received a telegram from Dr. J. D. Plunkett, the Chairman

of the Section, stating that he had been detained by the sudden illness of his wife, and regretted that he would be unable to be present.

Dr. A. N. Bell moved that the Secretary be instructed to express to Dr. Plunkett the regrets of the Section at his absence, and to request him to forward at once a copy of his address for publication. It was carried.

Dr. H. O. Marcy being compelled to read a paper in another Section, his paper was substituted for the first paper on the programme, the author of which was absent. Dr. Marcy read his paper on "The Coroner System in the United States."

The paper of Dr. George M. Sternberg, Lieut.-Col. and Surgeon U. S. Army, on the "Disinfection of Excreta," was read, in the absence of the author, by Dr. Peter H. Bryce, of Ontario.

Dr. C. W. Chancellor, Secretary of the State Board of Health of Maryland, then read a paper on "Simple Methods of Sewage Disposal," accompanied by the presentation of a model apparatus for the purpose of use in suburban residences.

The Secretary read a letter from Dr. Robert C. Davis, member of the Board of Health of the City of New York, stating that owing to illness, he regretted to be unable to be present to open the discussion on these papers, as announced.

Discussion being invited, Dr. Lyster, of the Michigan State Board of Health, remarked on the fact of the necessity of some definite action on the part of the Section for the protection of water supplies, both in wells and rivers, from the sources of pollution referred to in Dr. Chancellor's paper. He thought we should put ourselves on record as utterly condemning the use of the ordinary unprotected privy vault.

Dr. Bryce, while greatly interested in the manner in which Dr. Chancellor has sketched the different methods of sewage disposal, and in the method proposed for dealing with it in small quantities, which he could see might work very fully for separate houses, confessed that he had been disappointed in the want of success attributed by the reader of the paper to systems of sewage irrigation. Water carriage has such a vast advantage over all other systems in convenience, and in cleanliness, and in inoffensiveness about the residence or building, and with good modern plumbing may be made so perfectly safe to the occupants of the house, that we are practically compelled to accept it for all towns of any size.

It had been demonstrated that the separate system could be introduced for a town of 5,000 inhabitants, at a cost of from \$7,000 to \$9,000 per mile, with all necessary appliances for flushing automatically. The question of expense, therefore, is met. The only question is, in cases where there is not a large river with a strong current, what to do with the effluent. It did seem

to him that Dr. Chancellor had overstated the difficulties attendant upon treating this by irrigation. As an instance of how readily this might be done, he referred to the system in use by the London Hospital in Ontario. The entire plant, from beginning to end, cost only \$25,000, and it sufficed for the necessities of a population of 1,200 people. The separate system was adopted. The irrigation farm was only four acres in extent. One-third of this surface was used every day, so that each portion had two days of rest. The effluent flowed on to it, so thoroughly mixed by its rapid passage through the pipes, that it was absolutely fluid and left only a thin film on the surface, which when dry was raked in by a laborer. There had never been the slightest offensive odor from it, and chemical tests indicated complete nitrification of all the organic filth.

Dr. Chancellor, in closing the discussion, said that Dr. Bryce had evidently misunderstood him, as regarded the intent of his paper, which was not intended to take up the discussion of large systems of sewerage, but only of devices, where large systems are not available. His figures on the expensiveness of irrigation were with references to places in which it was absolutely necessary to prepare the ground by an elaborate system of double under drains. Very few places were so fortunately situated as London with its natural filter bed of sand close at hand. And even then he feared that in a few years it would be necessary for them to take in new ground for the purpose. This had been the experience in Berlin and other Continental cities. In regard to the purification of infected wells, he had often been able to accomplish it by having a quantity of chloride of lime placed in the well, allowed to remain a few hours, and the well then pumped out completely. By repeating this process two or three times, the water could often be completely purified. Of course, when it was practicable, he preferred to have such a well abandoned.

The next and last paper of the programme was read by Dr. G. W. Jenkins, of Kilbourne City, Wisconsin, under the title "Hygiene in the Rural Districts."

The suggestion contained in the paper that physicians could do much to improve the hygienic conditions in rural districts, by forming social clubs, which should meet from house to house, and before which demonstrations of truths familiar to hygienists, which would interest and impress the minds of the people, was considered a practical and valuable one by Drs. Lee, Lyster and other members.

The section was then declared adjourned, to meet at the time and place determined upon by the Association, in the year 1892.

BENJ. LEE, *Secretary*.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to
JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, SEPTEMBER 19, 1891.

HOW SHALL MEDICINE BE TAUGHT?

As the time for the opening of the colleges approaches, the methods of teaching again present themselves for discussion. Shall the teaching be by lectures, or recitations, or some other method?

By the recitation method the contents of a text-book can be very thoroughly learned by the student; the exact meaning of the language employed can be made clear. A text-book, to be of special advantage, must be accepted in its entirety, or practically so. All successful teaching is dogmatic. If the teacher lectures he may be dogmatic, but if he uses a text-book, he must surrender his dogmatism, his position as master, to the text-book, for there cannot be two masters in the same house. To use a text-book, and then make frequent additions to the text, or differ from it frequently, can only introduce confusion. The recitation method of teaching then necessitates the use of a text-book which can be accepted by the teacher as complete, explicit, and reliable. In what branches of medicine is it possible to find such text-books? In anatomy suitable works are available. Let us take GRAY. Now, where shall we find the genius who can quiz a class of 40 men through GRAY in 40 or even 60 hours? Assuredly the work would be much more superficially done than if even a mediocre lecturer had spent the time with the class.

In a recitation much time is necessarily lost in asking questions, explaining questions, and receiving slow responses, and much more is often aggravatingly lost in idle discussions of unimportant points, which cannot be altogether avoided. The recitation method is slow. On the other hand, the properly-trained lecturer studies for his class, and by doing the work for a hundred men becomes a time-saver and labor-saver of the greatest importance. A text-book in physiology might be found in LANDOIS, FOSTER, or even YEO'S manual. The science of chemistry is so far advanced, is so accurate, and free from theories, that it might be taught from a text-book, instead of by lectures. But there is not a book on medical chemistry which will answer the purpose.

If the practical branches are considered, just two will be found so far developed and reduced to such definite conditions as to admit of instruction by text-books, and these two are obstetrics and ophthalmology. The principles of surgery and general pathology might with advantage be taught from a book, but not so the practice of surgery, the practice of medicine, or gynecology. For the practice of medicine not a single text-book can be found to which a conscientious teacher would be willing to limit his class. Short, bare statement of great facts may be sufficient for one who has read widely, but they are barren to the student.

In the important matter of etiology, all our text-books are strangely deficient, and in that special branch of etiology, bacteriology, no text-book can keep up with the times.

The text-book is a voice from the dead. It is lifeless and can never be made to take the place of those great teachers, who through their individuality, have impressed, not themselves, but the great truths of medicine on the minds of their hearers, and imparted new life to them. Imagine MEIGS, FLINT, DALTON or GROSS with text-books in hand! The practical branches of medicine contain too much of the art to be successfully relegated to books for elucidation.

Medical education should aim to do more than merely implant facts. Medical culture is needed. A culture which shall enable the student and practitioner to take comprehensive views, to think broadly, to give to opinions and statements a proper weight, to realize the inherent deficien-

cies of his own information, to possess a frame of mind which is capable of receiving new discoveries. In such a scheme of education, the textbook plays a most pernicious part. It is essentially narrowing, and conducive to a condition of shallow bigotry. Much more culture can be imparted by a lecturer who is himself the possessor of broad views. The great field of medical literature should be thrown open to the student and he should be taught how to cultivate it. The many views of many minds is the great corrective of narrowness.

Aside from the question of text-books or lectures, there is another great branch of medical teaching which bids fair to come so far to the front as to throw completely in the background this other question.

The objective method of teaching medicine has made great strides lately, and is bound to become more and more prominent. To learn anatomy without dissecting is impossible. Physiology should never be taught without the aid of a laboratory to illustrate, at least, fundamental truths, and chemistry cannot be taught without a laboratory. To acquire an accurate knowledge of normal and morbid histology without the microscope is impossible. The same is true of bacteriology.

In the practical branches the objective method is gaining ground. Clinical instruction is the best instruction in these branches. If clinical material were sufficiently abundant to enable the diseases of the several organs to be presented systematically to students in the shape of clinical examples, it would be the ideal plan of teaching. In its absence, the didactic lecture must still be the means of systematic instruction, while the clinic avails for illustration. After all, the didactic lecture is much like a composite picture, the resultant of many details representing the same general condition, and not exactly resembling any of the individuals who have given origin to it. And like the composite picture the didactic lecture is most intelligible to those who are familiar with the originals. The importance of clinical teaching grows apace with improved methods of diagnosis and treatment. Refinements of diagnosis require illustration to make them understood. The existence and flourishing condition of the post-graduate schools for clinical instruction speak louder than all else for more and better clinical instruction by our undergraduate schools.

In the efforts to improve medical education, it should not be forgotten that the prime object of the schools is, or should be, to supply the community with capable, working physicians, and this cannot be accomplished without proper clinical teaching.

IS INEBRIETY A VICE OR A DISEASE?

The attempt to study scientifically the various departures of mankind from the rule of right living, brings up many interesting and difficult questions. When we no longer rest content with the simple fact of the choice of evil rather than good, but seek to know why such a choice is made, the boundaries between vice and disease no longer seem so fixed and definite as they were formerly thought to be. Especially is this true in regard to the subject under consideration. Very few, probably, who have studied the phenomena of drunkenness thoroughly and candidly, look upon the confirmed drunkard as merely the slave of a bad habit. There can be no doubt that the long continued abuse of alcohol brings about a diseased condition which aggravates the craving for the poison that caused it, and impairs the patient's power of self-control. So far, the question presents little difficulty, and there are probably few in the ranks of the medical profession, at least, who would not agree to the proposition that every drunkard is a diseased person.

When, however, we come to inquire how this diseased condition came about, the question is no longer so simple. Evidence is constantly accumulating that the practice of excessive indulgence in alcohol may itself, in its inception, be a symptom of disease, and the question has now come to be not as to the possibility of such a state of affairs, but as to its frequency.

The *North American Review* for September contains a discussion of the question "Is Drunkenness Curable?" by Drs. W. A. HAMMOND, T. N. CROTHERS, E. N. CARPENTER and CYRUS EDSON, which illustrates, to some extent, the divergence of views on this point. Dr. HAMMOND dwells, almost exclusively, on the influence of habit and opportunity in the making of drunkards. Dr. CROTHERS attributes over 60 per cent. of cases of inebriety to heredity, 20 per cent. to disease or injury preceding the use of spirits, 10 per cent. to brain and nerve exhaus-

tion, 5 per cent. to bad sanitary conditions, and says that "in a small percentage the causes are obscure and unknown," evidently implying that habit, the usages of society and the moral standards of the individual, have nothing to do with the matter. DR. CARPENTER takes the ground that "some men are born drunkards, some achieve drunkenness, and some have drunkenness thrust upon them."

The estimate of DR. CROTHERS as to heredity can be better appreciated in connection with the context. He says: "The parents and grandparents have been continuous or excessive users of spirits, or have been insane or mentally defective, or have been consumptive, or had rheumatism, gout, or some other profound constitutional disease, before the birth of the child." In view of the frequency of most of these conditions, it may be questioned if a majority of healthy persons could not find instances of one or more of them among the six persons included in two generations of ancestors. At the beginning of this century, probably nearly the whole male population of this country, aside from those whose means enabled them to drink wine habitually, could have been properly described as continuous or excessive users of spirits.

Without questioning the reality of the causes mentioned by DR. CROTHERS, it seems to us that habit and custom count for a good deal more than he is disposed to admit. The overwhelming preponderance of the male sex in the inebriates of this country does not seem easy to explain on his theory. Women are as much exposed as men to most of the influences he mentions; no such difference in favor of one sex is observed in other neuroses, nor in regard to the use of opium, and other stimulants and narcotics, in cases in which social influences do not bear with unequal force upon the sexes. The great rarity of drunkenness among the rural population of Mohammedan countries, and its almost universal prevalence in many savage races, so soon as the opportunity is offered, its varying prevalence in different communities, and in the same community at different times, go to show that the part played by pathological conditions in the beginnings of the alcohol habit is a subordinate one. The same thing is indicated by the ordinary course of inebriety. Although there are not a few instances in which a person who has previously been a total abstin-

er or a temperate drinker suddenly develops a tendency to get drunk, as a rule the drunkard begins as a moderate drinker, and the habit grows on him, like other habits, until it becomes one of habitual excess.

The question of the curability of drunkenness is of much less importance than its preventibility. A state of public opinion that would make the sale and consumption of alcoholic drinks thoroughly disreputable would do more than anything else to put an end to the evils of intemperance. Many excellent people would consider the remedy worse than the disease.

THE PUBLICATION OF SECTION WORK.

After the recent meeting of the American Medical Association, it was determined to attempt the publication of the work of each Section in consecutive numbers of *THE JOURNAL*. Fortunately, the committee of arrangements at Washington had prepared the official programme in the order of the original creation of the Sections. This enabled us to take up the work of publication in a proper serial order, beginning with that of Medicine. Up to and including this issue of *THE JOURNAL*, there have been published the papers read before the Sections on Medicine, Obstetrics and Diseases of Women, Surgery, State Medicine, and nearly all of the Section on Ophthalmology. As rapidly as this publication has taken place, the completed Sections have been republished in reprint form, and a few copies distributed to the members who took part in the proceedings by reading papers. This was done as a recognition of their active interest in the scientific work of the Association. It is much regretted that we were not in each instance placed in possession of the complete discussions which took place in the Sections. This will be provided for at the ensuing meeting. Another regret, and one that we have seriously felt, has been the shortness of type in *THE JOURNAL* office, which, in a number of instances, prevented our withholding matter for publication until proofs could be returned by authors of papers. To the uninformed about such matters we will say, a printing office should be restocked with type at the beginning of a new volume. Worn type and new type does not work together when mixed.

The method adopted in the serial publication of Section work does not allow us to give a great variety of matter to our readers in each issue of *THE JOURNAL*, but it does give to each member of the Association and *JOURNAL* subscriber a singularly valuable post-graduate course of reading. Subjects and departments in medicine are concentrated in a few numbers, and an opportunity is afforded of making a practical recognition of working members. Not only this, but their papers and discussions are rendered doubly valuable by reason of their easy reference. Those who are engaged in specialty practice will most fully appreciate this method of publication of their Section proceedings. Men who aspire to leadership and excellence in scientific researches will find in the Sections of the American Medical Association an arena that is unequalled as a place for the display of their best thoughts and work.

Specialty societies have their place in the professional field, and from them there are sent forth annual exhibits of studies and clinical observations of the greatest value. Thus it is that, semi-annually, the work of the Sections of the American Medical Association, and the great specialty societies reflect the professional conclusions of the most skilful men in our art. In this way the tally is made in professional progress.

PHYSICAL TRAINING REMEDIAL OF PSYCHICAL OBLIQUITIES.

At the Red Hill Reformatory, England, exists an institution, the aim of which is to improve the mentality and moral sense of young offenders by correcting their physical defects, and is known as "the criminal reform athletic school." A recent report makes a claim that 94 per cent. of the cases, retained a reasonable length of time, are recorded as cured. If the gymnastic reformation of the depraved is to be the treatment of the future, it will do away with the necessity of the remarkable suggestion, recently presented in the *Revue Scientifique*, as being the conception of a Californian physician. He proposes that those cases of mental insufficiency that lead to criminality shall have, by legal enactment, to pay the penalty of castration. He does not dwell much upon the direct or deterrent effects of this penal operation upon the criminal himself; the object to be gained is the prevention of transmitted,

hereditary defects. In other words, the criminally minded should not be allowed to propagate after their kind. The "moral," or fear inspiring, effect upon that class of scoundrels, who contemplate and deliberately plan the rape of children, the beating of their wives, bigamy, and the misleading of the weaker sex—not to specify other nearly equally repugnant forms of cowardly vice—ought to be very marked. Imprisonment has no fears for many of these wretches who come up time after time for trial regarding repetitions of the same offense. The *Press and Circular*, in an editorial comment, seems to favor the extension of castration as a punishment upon house-breakers, but is not in favor of having the morning papers adopting the term "castration," because the police reports, therein printed, would scarcely be "polite reading for the ladies at the family breakfast table." For example, that journal supposes, if Bill Sykes were to come up for sentence, and the verdict might be "that the prisoner be sentenced to ten years penal servitude and to be immediately castrated. This would not do at all; some new word would have to be found for expressing the latter part of the judgment on the irrepressible gentleman who disturbs our households at night."

"M. D., INDIANAPOLIS."

We note in the *JOUR. AM. MED. ASSOCIATION*, and in several other medical publications, an article with the above caption, in which it is stated that one S. E. L. SMITH, who was arraigned in Birmingham, England, for assuming the title of "M. D., Indianapolis." SMITH produced in court a document which gave him the said title. It was said the document cost SMITH thirty dollars. We have looked over the list of graduates of the two regular colleges of this city, and are prepared to say that neither of those institutions granted the degree. There are two irregular colleges here, and for them we are not prepared to speak; but the regular schools require four years' study and attendance on three courses of lectures of six months each, with preliminary education in the common school branches. The examinations are rigid, and money cannot purchase favors of these institutions.—*Indiana Med. Jour.*

We take pleasure in endorsing all that the editor of the *Indiana Medical Journal* says of the two regular schools of medicine in Indianapolis. Their character and the integrity of their managers is not questioned. Of the other two the

Illinois State Board of Health reports the diplomas of one recognized conditionally, and the other not recognized. The natural inference is that S. E. L. SMITH had a diploma from one of the latter institutions.

CREDITABLE.

The Illinois State Board of Health last week examined a recent graduate of the University of Berlin. This action is in accordance with the regulations of the Board in not recognizing diplomas from institutions in countries where the diploma does not entitle their holders to practice. This specially obtains in regard to Prussia, where the candidate has to pass the Staats Examen. The result in this instance was highly satisfactory, and creditable to the applicant.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

The Board of Health has for some time been engaged in a thorough investigation of the sources of pollution along the Croton watershed, in consequence of the somewhat unsatisfactory condition of the water, as shown by the analyses made by the chemists of the Board. The two great aqueducts now in use bring to the city a daily supply of about 150,000,000 gallons of water, which comes from Croton Lake, a body of water formed by damming the Croton River a short distance from the point where it flows into the Hudson. The Croton River brings water down into this lake from the hills of Westchester, Putnam and Dutchess counties, and near Croton Falls the river divides into three forks which are known as the East, Middle and West branches. Each of these is fed by numerous streams and brooks, many of them being of considerable size, and many of them having their independent storage reservoirs. The Muscoot River brings the waters of Lake Mahopac down into the Croton River. The East, Middle and West branches have each their great storage reservoirs, the first having the Sodom Dam and Mud River reservoirs, the second the Middle branch reservoir, and the third the Lake Glenead and Lake Gleneida reservoirs. The storage reservoirs of these three main branches of the Croton River are in turn supplied with the waters of a hundred lakes, small rivers and brooks from the north.

It is certainly as perfect a water-shed as can be found anywhere in this country. Its supply by nature is abundant and pure, and its channels for regulated distribution altogether admirable. But the beautiful country from which this grand supply of naturally pure water springs has, like all beautiful countries, become populated. The centers of population there are rapidly grow-

ing, and it is from this source that the menace to the health of this great city, which depends on this water-supply, comes. The situation is not particularly grave at present, but it is unquestionably likely to become so in the future unless suitable measures are taken in time; and hence it is that it is imperatively necessary that such legislative action should be taken as will protect the interests of New York in this very important matter. In the meanwhile, the city health department is doing all that it can to ward off threatened evils, and at a recent meeting it adopted resolutions calling upon the State Board of Health to cause to be reported as soon as possible to it the names and residences of all persons ill with a communicable disease who reside on the Croton watershed, and also to notify it of all deaths occurring on the water-shed, stating in every instance the cause of death and the residence of the deceased.

The chief engineer of the Croton Aqueduct has also made a report in regard to the contamination of the water supply, and the carefulness of statement which characterizes it is worthy of high commendation. In it, however, the fact is plainly recognized that the greatest danger to the quality of the city's water supply arises from the flow into the tributary streams of liquids charged with refuse matters from the most thickly populated portions of the water-shed. As to the contamination of the water in the reservoirs with organic matter, this is held to be a phenomenon of uniform occurrence in all newly flooded reservoirs. However carefully the ground may be cleaned before flooding, there will be vegetation left whose decay will liberate sulphuretted hydrogen, and so be a source of temporary contamination. Exposure to the air rids the water of the noxious gas, and the organic matter which may be held in suspension is not dangerous. On the whole, the quality of New York water is not altogether what it should be, and what it ought to be made by the interference of suitable legislation; but at the present time, at least, there is in it no serious danger to public health.

The Board of Health's summer corps of visiting physicians, reference to whose work was made earlier in the season, has completed its two months' service in the tenement house districts of the city. During this period these physicians visited over 30,000 houses and families, but it is stated that fewer cases of sickness were found than during any previous summer since this service has been established.

The free excursions of the St. John's Guild Floating Hospital have also now been discontinued for the season. This year no less than five trips a week have been made, a greater number than ever before; the boat starting on three days of the week from landings on the East River, and on two days from landings on the Hudson River. The full capacity of the floating hospital is 1,500, but this large number makes it somewhat crowded, and it usually carries from 800 to 1,100 mothers and children. Of course no cases of contagious disease can be taken, and a physician is always stationed at the gang-plank to see that none such are brought on board. The hospital barge is towed by a tug-boat, and as soon as the start is made most of the children are sent to the capa-

cious upper deck, where they run about and get the full benefit of the salt breezes. The trained nurse in charge of this deck has a watchful eye over all, and circulates among the mothers, giving many useful health hints and suggestions as to the proper care of their little ones. To many of the women she says, "I think baby would be better for a nice salt water bath," and the mother and child go below to the bath-rooms. There are five tubs, five spray baths for children, and two spray baths for women, with another trained nurse in charge of them, and many baths are given during every trip. The worst cases are carefully put to bed in two large, airy rooms on the lower deck, and the most of these are left at the seaside hospital of the Guild, where they remain for ten days or so. Besides the physicians and nurses, the working force of the floating hospital consists of a captain, pilot, six deck hands, watchman, engineer, two cooks, and ten waitresses. Two lifeboats are towed behind, in each of which sits a sailor, on the outlook for any child which may fall overboard.

After an invigorating sail down the beautiful bay and through the Narrows, the boat comes to anchor half a mile from the Seaside Hospital on Staten Island, and the patients destined for this institution are rowed ashore. Those remaining on the barge are then taken downstairs and given a bountiful dinner. The milk used for the children is the purest that can be obtained, and it is carefully sterilized and tested before it is put on board. The Seaside Hospital, which is beautifully situated almost at the water's edge, can accommodate over 250 patients, and the arrangement of the beds in its cool and lofty wards is quite novel. From the foot of the iron bedsteads used by the mothers rise two iron supports which curve above the bed like the davits on a ship, and from these a crib is suspended at right angles to the bed. The sick child thus hangs in the air immediately above its mother, and she can attend to its wants instantly, and without rising from her own bed. There are ten acres of land about the hospital, with a fine cedar grove, and with the most abundant facilities for sea bathing. Other institutions which prove of inestimable benefit to the children of the poor are the Summer Home of the Children's Aid Society, the St. George Sanitarium, and the Summer Branch of St. Mary's Free Hospital for Children, all of which are located on the Long Island sea coast.

P. B. P.

KANSAS CITY LETTER.

Vaginal Hysterectomy for Carcinoma—Insanity Following Rectal Operation—Methyl-violet for Cancerous Growths—A New College Organized—College Notes.

The meetings of the Academy of Medicine have of late been unusually interesting. At the last, Dr. J. F. Binnie, Professor of Pathology in the University, discussed the subject of

VAGINAL HYSTERECTOMY FOR CARCINOMA.

He first presented the history of a case successfully operated upon by himself seven months ago, exhibiting the specimen as well as slides showing the cancerous character of the disease, and then gave a table of 1,169

cases gathered from published reports and from private communication of hitherto unpublished operations; these figures gave a mortality of *less than twelve per centum*, the total number of deaths being only 137—in view of which it takes a bold man to say the operation is unjustifiable because of immediate danger. And the ultimate results are no less satisfactory—in fact they are rather surprising inasmuch as a careful study of cases operated upon years ago shows that *more than 50 per cent. of all cases operated upon permanently recover*. This is a somewhat remarkable showing, but it bears out Schauta's estimate of 47 per cent. permanent recovery and places the operation of vaginal hysterectomy far in advance of many procedures generally accepted as justifiable; for example, amputation of the breast for malignant disease, König's statistics giving only 23 per cent. of recoveries in the latter operation. After a thorough analysis of the subject Dr. Binnie formulated these conclusions:

1. Vaginal hysterectomy is a comparatively safe operation.
2. In many cases vaginal hysterectomy effects an absolute cure. Where it does not do so it generally gives relief from distressing symptoms.
3. The more localized the carcinoma, the sooner should total extirpation be done.
4. When it is surmised, but not positively known, that all the disease cannot be removed, the operation ought to be performed.
5. Adhesions in the upper part of the uterus, when there is cancer in the lower, call for at least, an exploratory laparotomy, and if the adhesions prove to be the result of inflammation, hysterectomy may be made.
6. Superficial extension of the disease over the vagina does not absolutely contra-indicate the operation.
7. Clamps, for the control of hæmorrhage, are probably as safe as ligatures, if antiseptic precautions are vigorously attended to; certainly their application is infinitely easier and more rapid.

Dr. George Halley, in discussing the paper, said he had made the operation in eight cases with but two deaths as the immediate result, and though there has been a return of the disease in two cases the recurrence has been in the mesentery and liver, and life has not been so miserable as it would have been with the terrible pains and offensive discharge of primary uterine carcinoma; besides, life has undeniably been prolonged from one to four years. In two of these cases there has been a radical cure; a number of years have elapsed and there has been absolutely no evidence of return; yet careful microscopic examination shows the disease to have been unquestionably cancerous in both cases. Involvement of the vaginal wall does not necessarily contra-indicate operation as in one case the vagina was extensively infiltrated and death would undoubtedly have occurred in a few months, but careful dissection of all affected tissues and vaginal extirpation prolonged the life of the patient almost three years; she died with but little suffering—always thankful for the temporary relief from horrible distress.

INSANITY AFTER RECTAL OPERATION.

Dr. Emory Lauphear lately reported to the Academy

the case of a woman, aged 40, suffering from pyosalpinx, and had hæmorrhoids with fissure; her general condition was bad—the patient nervous and emaciated, and troubled with obstinate constipation and some insomnia. She was put in the hospital for some weeks and improved greatly, the appetite becoming good, sleep excellent, bowels regular and loose, and the strength quite satisfactory—so an operation on the rectum was deemed advisable. Under chloroform, Dr. Lanphear removed the entire lower part of the rectum, with some hard, infiltrated connective tissue surrounding it, pulling healthy mucous membrane down to cover the denuded surface; iodoform was applied freely and the bowel packed with iodoform gauze, bichloride gauze and cotton over outside. She was put to bed without shock and with no subsequent bad symptom, such as pain, rise of temperature, etc. The wound healed by first intention everywhere except at one point where there was pus formation.

On the fifteenth day there was still some pus discharging, and considerable pain at stool, but patient had been gaining at least a pound daily in weight, the temperature was normal, bowels regular, and sleep satisfactory without hypnotics. The next day she became despondent, crying much; the next there was considerable incoherency with the melancholia, but under twenty grains of bromide of sodium she slept nine hours. The next morning she was a perfect picture of dementia; the next she was somewhat excited but passed into a stupid condition soon. The next morning she was apparently unconscious, pulse 60, respiration 16, and temperature normal; she swallowed food (milk and milk punch) and medicine nicely during the day. In the evening she was seen by Prof. J. M. Allen, also; he gave an unfavorable prognosis as he had some years ago a case of insanity following operation for fistula in which there was a fatal termination, with no discoverable cause. The next day witnessed no improvement; she began menstruating in the afternoon, and exhibited some evidence of pain and ovarian tenderness under pressure; temperature $99\frac{1}{2}^{\circ}$ F. On the next day the temperature began to rise, the respiration ran up to 56 per minute and marked emaciation became manifest. The record for the next morning was: temperature $103\frac{1}{2}^{\circ}$ F., pulse 140 and respiration 144 per minute! Of the accuracy of this observation, Dr. Lanphear said there would be no doubt as it was repeatedly verified during the next 30 hours, the patient dying at 2 P.M., of the following day. No autopsy was obtainable.

The probabilities are that the mental disturbance and subsequent cause were due to septic poisoning, but if so the manifestations of septicæmia were of a very peculiar character to say the least. One theory advanced was that the nerve-centers gave way simply from the reflex irritation coupled with the effect of the anæsthetic; in two cases of removal of the uterine appendages reported here some two or three years ago, insanity followed within a few days after operation—and one case has become hopelessly demented. Whether the case here mentioned would have proven an instance of post-operative insanity if the woman had lived is a question for speculation.

ANILINE DYES FOR CANCER.

Methyl-violet, after the method advocated by Moosetig

von Moorhof, is being extensively tried in this city for the cure of inoperable malignant growths. One case under the care of Dr. J. W. Perkins of St. Margaret's hospital showed some improvement and marked immunity from pain after each injection; the growth—sarcoma—was most painful, necessitating the hypodermic use of a half grain of morphine every four hours, but the patient was able to go from sixteen to twenty-four hours with no morphine whenever the pyoktain injections were made.

Other cases under Drs. Fulton, Block, Griffith, Binnie and others at St. Joseph's, All Saints', the German and City Hospitals have shown wonderful results. At the Academy, Dr. J. D. Griffith, Professor of Surgery in the K. C. Medical College, recently reported seven cases in which he had used the drug. Of the seven cases one died, two were (apparently) completely cured—patients exhibited to the Academy—and all the others are improving. Two cases were epithelioma of the face, one epithelioma of the cervix, one osteo-sarcoma of the upper and lower jaw, one adeno-sarcoma of the side of neck and face, the other two were sarcomatous tumors, inoperable. One of the cases presented adeno-sarcoma is 27 years of age, came under treatment some weeks ago, for a very large tumor of the right side of the face and neck; it was of a slow and painful growth, and presented all the symptoms of malignant growths of glands, and examination showed it to be a true adeno-sarcoma, involving the parotid and submaxillary glands. Treatment was begun by injecting twenty minims before and behind, the solution being 1 to 500, carefully sterilized, the face being thoroughly cleansed by antiseptic solutions to prevent the introduction of any material which might cause suppuration. The injections were repeated every other day and rapidly increased in quantity. In two weeks the tissues began to break down; the fluid contents were carefully aspirated and the injections continued, care being taken to throw the solution into the tissues around and not into the cavity in the growth. The tumor rapidly diminished in size as the injections were repeated and the quantity of fluid increased; at last three drachms of the solution were used every second day. There *never* was any pus present, the fluid withdrawn consisting simply of serum, broken down connective tissue, a few leucocytes and many cancer cells; the most careful examination failed to show any staphylococci or streptococci of suppuration. Soon the tumor shrank to almost nothing and now presents no trace of the malignant disease that promised to end his life in a short time.

The other case shown [osteosarcoma affecting the molar, superior maxillary and inferior maxillary] was treated in the same way, but with more difficulty, owing to the extreme hardness of the tissues; as only a few drops could be deposited in one place, many punctures had to be made and never could more than sixty minims be injected at one sitting; yet cure is seemingly complete.

In the fatal case, operation had been made some months ago for small epithelioma of the lip. An immense secondary growth sprang up, which, when patient was admitted to the hospital, hung down upon his breast; the parotid gland upon the left side was implicated as were all the glands along the sterno-cleido-mastoid. Upon the lower end of this enormous tumor there was a large ulcer to which some quack had been applying fresh frogs' skins (!) allowing them to remain until the stench would become intolerable. The man was suffering intensely, could not sleep, or eat, and had marked symptoms of septicæmia. But treatment was instituted by the usual injections, only in larger quantities—160 minims being finally used—and painting the ulcer with

the pure stick methyl violet [Merck]. The injections were made near the junction of the cancer with healthy skin as the solution could not be thrown into its body. The odor immediately disappeared, but in a few days the mass began to slough and on the day of death the entire mass dropped off leaving the face perfectly clear and free from cancerous tissue. Had the man not died from exhaustion and septic poisoning he probably would have been cured.

The question naturally arises whether this method of treatment is not, after all, about the same as that of Marsden's paste, the ointment of sorrel, etc., used by "cancer doctors." Instead of being applied externally, it is injected, causing death of the malignant growth without suppuration, simply because it is used hypodermically. The sloughing in Dr. Griffith's last case presents the clinical aspects of cancers treated by means of paste. It is not at all unlikely that pyoktanin has no specific action, and that the same result might be obtained by the injection of a strong infusion of either *Oxalis acetosella* or *Rumex acetosa* ["horse-sorrel"], or even of binoxalate of potash or oxalic acid. S.

MISCELLANY.

MEDICAL SOCIETY OF VIRGINIA.—The twenty-second annual session of the Medical Society of Virginia will convene in the hall of the Young Men's Christian Association, in the city of Lynchburg, Va., at 8 P. M., Tuesday, October 6th, 1891, and will continue in session through Wednesday, Thursday, and probably a part of Friday.

On entering the hall each Fellow, Honorary Fellow, Fraternal Delegate and Invited Guest should register his name, postoffice, etc., in the book for that purpose, which will be on one of the desks of the Recording Secretary.

Tuesday night's session will be open to the public. It will be called to order at 8 P. M. by the President, Dr. William W. Parker, of Richmond, Va. After prayer, the address of welcome will be delivered by Dr. H. Gray Latham, of Lynchburg, Va.

The address to the public and profession will then be delivered by Dr. Chas. M. Blackford, of Lynchburg, Va., his subject being "Medical Education as It Was; as It Is; and as It Should Be."

The Committee on Nomination of Applicants for Fellowship will make their report, and at once the vote will be taken on the nominations. Each gentleman, as soon as elected, becomes a Fellow, and is entitled to all the privileges and benefits of the Society.

Such other business of a general character as can be disposed of may then be introduced, including motions or resolutions that have to be referred to committees, reports of officers, announcements, etc.

Ex-President and Honorary Fellow, Hunter McGuire, M.D., LL.D., etc., of Richmond, Va., during the last session, authorized the announcement that he would offer a prize of one hundred dollars for the best original essay on pyelo-nephritis, presented by a Member or Fellow of either of the State Medical Societies of Virginia, West Virginia or North Carolina, of each of which he is an Honorary Fellow. All essays offered in competition must be considered as under the control of the Medical Society of Virginia or its Committee on Publications. The essay to which the prize is awarded will be published in the transactions of the Medical Society of Virginia and in such regular medical journals as may desire it.

The conditions of the competition are that the competing essays must be in the hands of the Recording Secretary of the Medical Society of Virginia by the first day of September, 1891. They must be type-written or printed. Each one must be designated by a motto on MS. (not by the author's name or other mark by which

the identity of the author is made known), and accompanied by a sealed envelope, with the adopted motto on the outside, and a card inside, giving the name and post-office address of the author. In advance of the session, the several competing essays are to be examined by a committee appointed by the President of the Medical Society of Virginia. This committee will report the two best essays in their hands, each of which is to be read before the Society, and the prize will be awarded to the one that a ballot vote may determine to be the best.

It is understood that either the Examining Committee or the Society shall have power to determine whether or not either of the essays possesses sufficient merit to entitle the author to the prize.

The following resolution, introduced last year (see Transactions 1890, pages 291-295), requires action during this session:

By Dr. George T. Walker, of Vinton:

Resolved, That the President of the Medical Society of Virginia appoint a committee, consisting of three Fellows, to consider the practicability of designating a time during each annual session, for the holding of clinics, and for clinical instruction, and report at the next annual session.

Committee on above: Drs. Geo. T. Walker, A. C. Palmer and Wm. T. Walker.

Practically bearing on the same subject, Dr. J. N. Upshur of Richmond moved (see Transactions 1890, page 311), that a committee of three Fellows be appointed, to report during the session of 1891, as to the propriety of recommending that a portion of some day of each annual session be set apart for the reports of cases, asking advice, etc.

Committee: Dr. J. N. Upshur, of Richmond; Honorary Fellow Dr. J. L. Ashton, of Dallas, Texas, and Dr. Thomas P. Mathews, of Manchester, Va.

During the session of 1890 (see Transactions 1890, pages 292-295), Dr. Hugh M. Taylor, of Richmond, Va., introduced a resolution to do away with the present system of annually appointing Reporters on Advances in the several departments of medical science, and in lieu thereof select annually some subjects for full investigation and discussion during the succeeding annual session, appointing several Fellows to report on given subdivisions of the subjects, so that the several reports or papers by different authors, when systematically arranged for publication in the Transactions, will practically form one continuous treatise or monograph on each of the several subjects so selected.

After full discussion, on motion by Dr. J. F. Winn, of Richmond, a committee of five Fellows was ordered to appointed to take the whole subject under advisement and report during the annual session of 1891.

The President appointed Drs. J. F. Winn and Hugh M. Taylor, of Richmond; I. S. Stone, of Washington, D. C.; Honorary Fellow Dr. Benjamin Blackford, of Staunton, and Dr. John Grammar, of Halifax C. H.

On Wednesday morning, October 7th, at 10 o'clock, the Society will be called to order. Business of a general character will be in order until 11 o'clock, when the President, Dr. William W. Parker, of Richmond, will deliver the annual address of the President.

The subject for general discussion, Acute and Chronic Dysentery, will then be called. The subject will be opened by a paper by the leader, Dr. P. B. Green, of Wytheville, Va. Dr. Wm. J. Crittenden, of Unionville, Va., will follow with a paper having the same title. Honorary Fellow Dr. Bedford Brown, of Alexandria, Va., will follow with a paper on "Dysentery Viewed as a Septic Disease, and Treated by Antiseptics." After this paper, the discussion will be open to Fellows, Delegates and Invited Guests, in the order of their recognition upon the floor by the chair, the right of closing the discussion being accorded to the leader, Dr. Green.

The afternoon meeting will be consumed in the election of officers, including the nomination to the govern-

or of one to fill the place of Dr. T. M. Bowyer (resigned) on the medical examining board of Virginia from the sixth congressional district; the selection of the subject for general discussion during the twenty-third annual session, and the leader in the discussion; the election of a Fellow to deliver the annual address to the public and profession; the selection of place and time for holding the twenty-third annual session, etc.

The meeting at night will be called to order at 8 p.m.

Reports on Advances in the Respective Departments of Medicine and Surgery will be called for in the following order, and continued as the order of business through Thursday, or until completed:

1. *Anatomy and Physiology*.—Dr. Paul B. Barringer, of University of Virginia, reporter.

2. *Chemistry, Pharmacy, Materia Medica and Therapeutics*.—Dr. Benj. Harrison, of Richmond, Va., reporter. In this Section the following papers will be read:

(a) The Place of the Turkish Bath in the Treatment of Disease. By invited guest, Dr. Charles H. Shepard, of Brooklyn, N. Y.

(b) Pharmacy and Its Practical Relation to the Profession. By Dr. S. J. Baker, of Bedford City, Va.

3. *Obstetrics and Diseases of Women and Children*.—Dr. Herbert M. Nash, of Norfolk, Va., reporter. In this Section the following papers will be read:

(a) Puerperal Eclampsia; Its Etiology and Treatment. By Dr. J. T. Graham, of Wytheville, Va.

(b) Etiology and Pathology of Puerperal Inflammations, illustrated with specimens. By invited guest, Dr. Thomas A. Ashby, of Baltimore, Md.

(c) Retro Displacements of the Uterus. By fraternal delegate from Medico Chirurgical Faculty of Maryland, Dr. H. P. C. Wilson, of Baltimore, Md.

(d) Recognition of Operative Cases in Gynecology by the General Practitioner. By invited guest, Dr. Joseph Hoffman, of Philadelphia.

(e) Remarks on Salpingitis and Peritonitis—the Result of Gonorrhoeal Infection. By honorary Fellow, Dr. George Tucker Harrison, of New York, N. Y.

4. *Practice of Medicine*.—Dr. Lewis E. Harvie, of Danville, Va., reporter. In this Section the following papers will be read:

(a) Importance of the Microscope to the General Practitioner as an Aid to Diagnosis and Correct Medical Treatment, with some Demonstrations in Bacteriology. By fraternal delegate from the Medical Society of Tennessee, Dr. James E. Reeves, of Chattanooga, Tenn.

(b) Hemorrhoids and Their Treatment. By Dr. J. N. Upshur, of Richmond, Va.

(c) Symptomatology and Treatment of the Chronic Forms of Nephritis. By Dr. William C. Dabney, of University of Virginia.

5. *Surgery*.—Dr. Thomas M. Bowyer, moved to Sioux Falls, S. Dak., reporter. In this Section the following papers will be read:

(a) Present Aspect of Cerebral Surgery. By invited guest, Dr. Landon Carter Gray, of New York, N. Y.

(b) Perineal Operations. By invited guest, Dr. Joseph Price, of Philadelphia, Pa.

(c) Concussion of the Lungs. By invited guest, Dr. B. A. Watson, of Jersey City, N. J.

(d) A Successful Myomectomy for Parasitic Tumor. By Dr. I. S. Stone, of Washington, D. C.

(e) A Plea for Closer Study of the Principles of Surgery by the General Practitioner. By Dr. Geo. Ben. Johnston, of Richmond, Va.

(f) Some Subject Connected with Orthopaedic Surgery. By invited guest, Dr. A. M. Phelps, of New York, N. Y.

(g) Treatment of Goitre by Electrolysis. By Dr. Chas. M. Shields, of Richmond, Va.

6. *Ophthalmology, Otology and Laryngology*.—Dr. J. Herbert Claiborne, Jr., of New York, N. Y., reporter.

[Dr. Claiborne will report on Ophthalmology. Dr. John Dunn, of Richmond, Va., has been appointed by

the president, by request, to report on Otology and Laryngology.]

In this Section the following papers will be read:

(a) Ophthalmology in Ancient Egypt. By Dr. W. H. Baker, of Lynchburg, Va.

(b) Some Personal Observations on Cataract Operations. By invited guest, Dr. A. W. Calhoun, of Atlanta, Ga.

(c) Mistaken Impressions about So-called Nasal Catarrh. By Dr. Joseph A. White, of Richmond, Va.

(d) Some Suggestions about Cataract Operations. By Dr. Joseph A. White, of Richmond, Va.

7. *Neurology and Psychology*.—Dr. William F. Drewry, of Petersburg, Va., reporter. In this Section the following papers will be read:

(a) Hereditary Chorea. By invited guest, Dr. Wharton Sinkler, of Philadelphia, Pa.

8. *Hygiene and Public Health*.—Dr. W. T. Oppenheimer, of Richmond, Va., reporter. In this Section the following papers will be read:

(a) The Drink Problem from a Medical Point of View. By invited guest, Dr. T. D. Crothers, of Hartford, Conn.

(b) The Drink Problem from a Medical Point of View. By Dr. Frederick Horner, of Marshall, Va.

(c) What is to be Done with our Criminal Lunatics? By Dr. J. T. Graham, of Wytheville, Va.

Several gentlemen have indicated their intention to present papers, but do not authorize the Executive Committee to announce the fact. Hence all such papers as may hereafter be prepared will be classified as Voluntary Papers, and will be called for in the order of their presentation after the completion of the above arranged order.

By a resolution adopted in 1884, not more than thirty minutes is allowed to the reading of any paper, whatever may be the length of manuscript, and extempore remarks must not exceed fifteen minutes.

The Medical Examining Board of Virginia will hold a semi-annual meeting in Lynchburg October 6th, 1891, at 8 p.m., preliminary to the examination of candidates (to begin next morning), for license to practice in Virginia. All letters of inquiry about this board should be addressed either to its Secretary, Dr. Paulus A. Irving, of Farmville, Va., or to its President, Dr. Hugh M. Taylor, of Richmond, Va.

The Local Committee of Arrangements, Dr. C. E. Bussey, of Lynchburg, Va., Chairman, is using every effort to make this session one of special pleasure and profit to those who may attend.

The Committee on Accommodations, Railroads, etc., Dr. John W. Dillard, Lynchburg, Va., Chairman, reports the following hotel rates:

Norvell-Arlington Hotel, corner of Church and Eighth streets, \$2.25 a day.

Lynch Hotel, corner Main and Ninth streets, \$2 a day.

National House, Main, between Ninth and Tenth streets, \$1.50 a day.

Railroad Rates.—Baltimore & Ohio—Card orders from points in Virginia to Staunton or Lexington at two cents a mile each way. Fellows, Delegates, etc., needing orders over this railroad, to secure tickets, should write at once to the Recording Secretary of the Society.

Chesapeake & Ohio—Round trip tickets from all principal points to Lynchburg or to Charlottesville, four cents a mile. If by way of Charlottesville, add \$3 to secure round trip from Charlottesville to Lynchburg and return, ticketing through to Lynchburg.

Richmond, Fredericksburg & Potomac R. R.—From Quantico and intervening depots to Richmond and return, about four cents a mile, round trip, according to "Special Round Trip Excursion Tariff," in effect since February 1st, 1890.

The Norfolk and Western, the South Atlantic and Ohio, the Richmond and Danville, the Lynchburg and Durham, the New York, Philadelphia and Norfolk, the Atlantic Coast Line, the Atlantic and Danville, will

charge five cents a mile, round trip, to connecting points. These rates are, in general, about the usual summer excursion round-trip rates.

The exhibition of surgical instruments, pharmaceutical preparations, etc., promises to be more than usually attractive. Parties wishing space should apply to the Chairman of the Committee on Exhibits, etc., Dr. Frank Canim, of Lynchburg, Va.

The number of applications for Fellowship received indicates that the addition to the membership will be very large. Fellows should induce their eligible friends to forward their applications at once.

Fellows should forward amounts due to the Treasurer, Dr. Richard T. Styll, Hollins, Roanoke county, Va., which is a postoffice money-order office, until October 5th; after that to Lynchburg.

HUNTER MCGUIRE, M.D.,

Chairman Executive Committee, Richmond, Va.

LONDON B. EDWARDS, M.D.,

Recording Secretary, etc., Richmond, Va.

AMERICAN PEDIATRIC SOCIETY.—The third annual meeting of this Society will be held in Washington, September 22, 23, 24 and 25, 1891, at the Arlington Hotel, Vermont Ave. and H St., Parlor 206.

President—T. M. Rotch, M.D., 197 Commonwealth Ave., Boston, Mass. First Vice-President—V. C. Vaughan, M.D., Ann Arbor, Mich. Second Vice-President—Joseph O'Dwyer, M.D., New York City. Treasurer—Charles Warrington Earle, M.D., 535 Washington Bd., Chicago, Ill.

Physicians are cordially invited to be present.

Tuesday, September 22, 8 P.M.

Reading of minutes of last meeting. General business.

1. Address of the President.
2. How to prevent Complications and Sequelæ in Scarlet Fever, J. Lewis Smith, M.D., New York.
3. Discussion on the Diagnosis of Pneumonia in Infancy and Early Childhood.

a. The most diagnostic symptoms of the early stage of lobar pneumonia, and the differential diagnosis from such diseases as Meningitis, Malaria, Scarlet Fever, etc. T. S. Latimer, M.D., Baltimore.

b. The diagnosis of consolidation of the lung from effusion (serous or purulent), and the differential diagnosis between Lobar Pneumonia and Broncho-Pneumonia, F. Forchheimer, M.D., Cincinnati.

c. The diagnosis of Broncho-Pneumonia (acute and chronic), from Tuberculosis, William Osler, M.D., Baltimore.

d. The diagnosis of Broncho-Pneumonia from Bronchitis, also the Temperature Range in Acute Pneumonia, both Broncho and Lobar, L. Emmett Holt, M.D., New York.

e. Remarks by A. Jacobi, M.D., New York, and by W. P. Northrup, M.D., New York.

f. General Discussion.

Wednesday, September 23.

9 A.M. Breakfast with the President at the Arlington.

11 A.M.—2 P.M.:

1. Demonstrations.
 - a. A Specimen of Congenital Heart Disease, William Osler, M.D., Baltimore.
 2. Manifestations of "La Grippe" in Children, Charles Warrington Earle, M.D., Chicago.
 3. The Treatment of Laryngeal Diphtheria by Calomel Sublimations, Dillon Brown, M.D., New York.
 4. Further Report on Submembranous Local Treatment in Pharyngeal Diphtheria, A. Seibert, M.D., New York.
 5. A Case of Ulcerative Catarrhal Dysentery, W. D. Booker, M.D., Baltimore.
 6. Stricture of the Oesophagus occurring in Children, with Report of a Case, F. E. Waxham, M.D., Chicago.
 7. A Case of Pulmonary Abscess—operation and re-

covery, with remarks, Francis Huber, M.D., New York. Thursday, September 24, 9 A.M.—2 P.M.:

1. Demonstrations.

a. Exhibition of Laryngeal Tubes for the Performance of Forcible Respiration, J. O'Dwyer, M.D., New York.

2. A Study of Fifty Cases of Chorea, Samuel S. Adams, M.D., Washington.

3. A Study of 140 Cases of Heart Disease in Children (by invitation), Floyd M. Crandall, M.D., New York.

4. Dysentery in a Boy of 11 years—presence of *Amœba Coli*, H. Lafleur, M.D., Baltimore.

5. Scorbutus in Children, W. P. Northrup, M.D., New York.

6. Chronic Nephritis in Children, Henry Jackson, M.D., Boston.

7. Two Cases of Acute Primary Nephritis in Infants, L. Emmett Holt, M.D., New York.

8. Scarlatinal Nephritis in Children, J. Lewis Smith, M.D., New York.

9. The Application of Gavage in the Treatment of Uncontrollable Vomiting in Infants (by invitation), Charles G. Kerley, M.D., New York.

10. The Association of Congenital Wry-neck and Facial Hemiatrophy, William Osler, M.D., Baltimore.

11. Tubercular Ostitis of the Hip, originating in Colorado, John M. Keating, M.D., Philadelphia.

12. A Case of Slow Heart in an Infant, terminating in Fatal Syncope, A. D. Blackader, M.D., Montreal.

8 P.M. Dinner at the Arlington.

Friday, September 25.

9 A.M. Report of Committee of Council on Nominations for Office and Membership.

12 M. Executive Meeting.

1. The Etiology of Stomatitis Aphthosa, F. Forchheimer, M.D., Cincinnati.

2. Perityphlitis in the Young, J. Henry Fruitnight, M.D., New York.

3. Intussusception, L. Emmett Holt, M.D., New York.

4. A Case of Congenital Cretinism, C. W. Townsend, M.D., Boston.

5. A Further Contribution to Cirrhosis of the Liver in Childhood, with Post-mortem Notes and Microscopic Studies, W. A. Edwards, M.D., San Diego, Cal., and W. M. Gray, Microscopist, Army Medical Museum, Washington, D. C.

The reading of papers will be limited to twenty minutes.

Members expecting to be at the breakfast on September 23, are requested to notify the President (Dr. T. M. Rotch, 197 Commonwealth Ave., Boston) of their intention on or before September 15.

W. D. Booker, M.D., Secretary, 851 Park Ave., Baltimore, Md.

[Members will please take notice that the correct hours for holding the Pediatric Sessions are those stated in this Programme, and not necessarily as may appear in the general programme of the Congress, which will also be sent to them, and which were merely provisional.]

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from August 29, 1891, to September 11, 1891.

Major Samuel M. Horton, Surgeon U. S. A., is relieved from further duty at Ft. Adams, R. I., and will proceed to San Diego, Cal., and report to the commanding officer for duty at that post.

Capt. L. W. Crampton, Asst. Surgeon U. S. A., is granted leave of absence for fifteen days.

Surgeon David L. Huntington, Surgeon Henry McElderry, Asst. Surgeon Walter Reed, Asst. Surg. Charles M. Gandy, appointed members of a board of medical officers to meet in New York City, October 1, 1891, for examination of candidates for admission into the Medical Corps of the Army.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Two Weeks Ending September 12, 1891.

Surgeon Howard Wells, ordered to special duty in fitting out the new naval hospital at Portsmouth, N. H.

Surgeon Jno. H. Hall, ordered before the Retiring Board, September 19.

Surgeon Jno. W. Ross, ordered, in connection with present duty, member of Board on Labor Employment.

ORIGINAL ARTICLES.

ORTHOPEDIC SURGERY AS A SPECIALTY.

The President's Address, delivered before the American Orthopedic Association at Washington, D. C., Sept. 22, 1891.

BY A. B. JUDSON, M.D.,
OF NEW YORK.

A flourishing medical society sometimes divides into Sections. It is an involuntary process, or at least one to which the members are forced by the necessity of thoroughly accomplishing the objects of the society. The process may be called an analysis. In the present instance, however, if I understand the organization of the Congress of American Physicians and Surgeons, we have a synthesis. A number of societies voluntarily combine to secure ends which were not contemplated at the beginning of each. A division of labor having been made, according to which each society has its special work to do, it is proper and useful for the societies to meet together for co-operation. Let us, therefore, briefly consider some of the salient features which mark our specialty of orthopedic surgery. A better knowledge of ourselves will put us in more quick relation with other workers, both general and special, and enable us better to do our humble part in the grand plan.

In common with other specialists we occasionally hear that we are limited in the possible range of our achievements. The limitation is, however, entirely voluntary, and the work within these limits is practically inexhaustible. If we were not so busy, we might perchance be troubled because we are not always and exactly understood. The sign before an orthopedic hospital in New York is supposed by some of the passers-by to indicate a homœopathic institution. I am probably not alone in having been asked to perform the minor surgical operations of the chiropodist. Many, even among the learned, suppose that the latter part of our name is derived from the Latin word for *foot*, instead of from the Greek for *child*. We are also confounded in the minds of some with the instrument-makers. I mention these things in passing, without a serious thought. If they exist, like morning mist, they will pass away.

It is well, however, to recognize the fact that our practice is comparatively lacking in popular qualities. We have no critical, capital, or brilliant operations. What of brilliancy is there in keeping a limb in such an attitude that the weight of the body in locomotion shall be a favorable, instead of an unfavorable agent, until the natural growth of the member results in comparative symmetry; or in controlling the environment of the diseased joint and the patient, so that the natural processes of recovery and repair shall have their triumph, while the limb is daily growing in symmetry and ability with the growing child? This is not bold surgery, but there is great pleasure in watching and reverently assisting these constantly recurring natural miracles. And will any of us forget the delightful friendships made among our little patients, their pretty bashfulness, their ready confidence, their irrepressible cheerfulness, their graceful acceptance of what is, alas, inevitable? The combination in them of childish and heroic qualities is a daily wonder. To watch them at play is like a dream in which the birds and wild flowers are enacting a tragedy and improving the precepts of Stoic philosophy.

Our practice is not only lacking in brilliant achievements, but it is also uninviting, because, as a rule, our patients do not make absolute recoveries. There is always, or nearly always, a residuum of disability and deformity, and in this is to be found, perhaps, one reason why our specialty has existence; for what general practitioner would lightly assume the care of a case so exceptional in his practice, and so momentous as those which fall into our specialty?

The why and the wherefore of specialties, in general, and ours, in particular, are questions of interest. Some will say that we have a natural aptitude for mechanics, an inherited preference for slow and sure methods, compared with those that are quick and uncertain, or an inborn reverence for what is physically demonstrable. These personal characteristics may explain why some of us are orthopedists, but I believe the reason why our specialty exists and thrives is to be found in the desire of the public, the final arbiter, that experts should be invited to bear the responsibility of orthopedic cases.

One very attractive feature of orthopedic practice is its *reality*—for want of a better word. It is especially the domain of physical demonstration, where the acceptance of pathological doctrine, as well as therapeutic precept, must be preceded by absolute proof. Here subjective symptoms are forgotten in the presence of objective signs. The data for diagnosis are visible, palpable and measurable. Treatment is by forces whose action is nicely directed, increased, diminished, and accurately measured. The very weight of the body is duly considered in trauma and therapeutics, and finally the results of treatment are recorded in degrees of a circle and fractions of an inch. Dealing thus, as we do, with physical realities, it is well for us to keep our eyes open to the moral verities also, which no less form part of the tissue of our daily professional work. Let us remember that diligence is the price of success, and that the only desirable success is that which is reached by the rejection of error and the loyal recognition of truth.

Since our last meeting, there has occurred the death of one of our Corresponding Members, whose hostility to error might in all friendly criticism be called intemperate—one whose diligence and devotion to the interests of his patients make him an exemplar worthy of our affectionate remembrance. But I will not trespass on the subject of the first paper of our session, which is by Dr. A. J. Steele, of St. Louis, on the orthopedic work of the late Mr. Thomas, of Liverpool.

FLUORESCEIN AND FLUORESCIN.

Read in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5-8, 1901.

BY FRANK TRESTER SMITH, A.M., M.D.,
OF CHATTANOOGA, TENN.

These recent additions to our materia medica are closely allied chemically, both being products in the distillation of coal tar.

They are of use from their faculty of coloring abraded surfaces of the cornea, thus enabling us to locate such abrasions rapidly and accurately. To the oculist this is of but little assistance, as he can readily diagnose these conditions by the methods now in use, and yet in some cases it is of assistance even to him, as in the extraction of small foreign bodies where we must get the substance between us and the iris, or against the black pupil. In these cases, the green ring around the offending material enables us to see it in any position. Likewise, in cases where we have much photophobia, we can tell more quickly and easily to what extent the cornea is involved.

In no other condition than that of abrasion of the cornea is any effect seen, and the action of the solution is limited to the corneal tissue.

Thus, it will discolor the cornea in traumatism with or without a foreign body being present, and in ulcers of the cornea. In interstitial keratitis it has no effect, also in inflammations of the other structures of the eye. In two cases of glaucoma no effect was produced, as has been claimed by some.

From the foregoing, it will be seen that it will be most serviceable to the general practitioner who is not accustomed to these cases.

Another use to which I want to call your attention especially, and to which I have seen no reference in any of the articles that have been published on this subject, is in testing whether a stricture of the nasal duct is impervious or not. The needle of a Knapp's lachrymal syringe is inserted into the punctum, and the solution forced through the canaliculus into the lachrymal sac. If there is the least opening through the stricture, some of the green solution will be found in the nose and can be blown out on the handkerchief. The diagnosis is thus much easier than when a clear solution is used.

Its use has been suggested as a sign of death, as the cornea of the dead will take the staining, while that of the living will not, except in the conditions before mentioned, and then the cornea would be but partially discolored.

Most writers have used only fluorescein, and some have failed to get the effect from fluorescin, but in my experiments I have not been able to see any difference between the two drugs.

Fluorescein is a light brownish-yellow powder, insoluble in cold, very slightly soluble in hot water, but more freely soluble in an alkaline solution; the addition of gr. vijss sodium bicarb. dissolving 10 grs. in an ounce of water. This is the solution in common use. It is of a dark brown color. The addition of water turns it green, and from the surface we get a beautiful fluorescence.

Fluorescein is manufactured by heating resorcin and phthalic anhydride to 195° or 200° C. (385° to 392° F.). It is of acid reaction. When freshly precipitated it is readily soluble in ether and alcohol, not so easily when crystallized. Acids may be present as impurities, and are readily detected by greater solubility.

Fluorescin is a yellow powder made by heating fluorescein with a solution of caustic soda and zinc dust. In solubility it is similar to fluorescein, into which it is readily converted by oxidizing agents.

Gr. vijss sodium bicarb. dissolves gr. x in an ounce of water. The solution is dark brown and turns green on the addition of water, with fluorescence. Its behavior on the abraded cornea is exactly similar to that of fluorescein.

In conclusion I would say that we have here agents of some value, especially to those not accustomed to eye affections.

The solutions are not painful in the least, either to the normal or to the inflamed eye. They are also non-irritating. I have used them in cases where the eyes were so irritable that no solution (except salt water or a solution of boracic acid) could be borne without pain and increased redness, and there was not the slightest irritating effect.

There are no bad after-effects. The coloring matter is gradually diffused through the corneal tissue and absorbed, this taking from one to several hours according to its amount.

They are of value only in diagnosing corneal abrasions (ulcers, foreign bodies, abrasions), while in other affections their effect is *nil*.

As a sign of death the solutions may have a proper place.

In testing the permeability of strictures of the nasal duct it is of assistance.

In my experiments I am indebted to Mr. F. Voigt and to Dr. R. L. Randolph for courtesies shown. Mr. Voigt worked out the solubilities and furnished the facts concerning the pharmacology of the drugs.

AN EXPERIMENTAL STUDY OF THE COMPARATIVE MYDRIATIC EFFECT OF ATROPIA AND HOMATROPIA.

Read in the Section on Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY HORACE M. STARKEY, M.D.,
OF CHICAGO, ILL.

Among the notable "anomalies of refraction" in the few years just past is the great divergence of opinion among ophthalmologists as to the comparative reliability of atropia and homatropia as mydriatics. It has been surprising to read the varying statements of different well-qualified observers as to the effect produced by the former of these agents; and particularly surprising is it to those who use homatropia with satisfaction to themselves and to their patients to find this drug pronounced absolutely unreliable. It is unnecessary to mention particular articles on the subject. We all recall many such. We also, many of us, recall the discussions that have occurred in this Section for several years past, and particularly at the meeting last year, when the discussions constantly returned to two topics, upon each of which the greatest diversity of opinion existed—namely, the advisability of correcting low degrees of astigmatism and the value of homatropia. On the latter question the members present seemed to be about equally divided between three opinions, all maintained with equal positiveness and tenacity. The first held that for suspending accommodation homatropia is utterly unreliable, and never should be used; the second, that it is generally reliable, and may, in

practically all cases, be used instead of atropia; while the third held the intermediate ground that while homatropia has a wide range of usefulness, there is quite a proportion of cases in which it is insufficient to paralyze accommodation. At that time the writer mentioned an anomalous case occurring in his own practice in which atropia, used thoroughly for a week, failed to relax accommodation, and in which the additional use of homatropia four or five times within an hour caused entire suspension of that function.

These opinions cannot all be correct, and it would seem that sufficient careful experiment and observation should definitely settle the value of this or any drug. There is no doubt as to the superior availability of homatropia in diagnosis if only it can be used with certainty.

To assist in establishing the place which homatropia should hold as a mydriatic, the writer has, during the past year, made a number of careful observations.

These observations have been made upon young patients seen in private practice, and for the most part upon cases presenting the most difficult features for examination.

A few of these, owing to the short stay of the patient in the city, or from some other unavoidable cause, are not as complete as desired, but in every case, so far as the observation extended, it was made with great care and conscientiousness.

Each observation was made as follows: At the first visit of the patient the usual record was made of the condition of eyes and appendages, apparent refraction, vision, and whether the latter could be improved by lenses or not, etc.

The eyes were then subjected to the influence of homatropia. For this purpose a fresh 1 per cent. solution was employed, and of this, one drop was instilled into each eye five times in the course of fifty minutes, and the examination commenced in one hour from the time of first instillation. A record was made of the time of each instillation, and of the time of commencing the examination. The second instillation was made about five minutes after the first; the third about fifteen minutes; the fourth twenty-five minutes, and the fifth fifty minutes after the first, the examination being commenced about ten minutes after this last. A record was made of the state of the refraction, and the patient directed to return the next day. In the meantime, a drop of atropia sulph. solution, strength four grains to the fluid ounce, was to be instilled in each eye two times that evening, about three hours apart, and again two times the next morning, with the same interval.

When practicable, the atropia solution was continued for two or three days, with daily notings of condition of refraction, and in some cases, where there were other indications for atropia, this was continued for several weeks.

TABLE OF CASES.

No.	Age.	Sex.	Condition for which Relief is Sought.	Vision.		Apparent Refraction.		Hom. Used.	Refraction Under Homatropia.

NOTE.—When ? sign is placed, vision was not improved by any glass.

The state of refraction was in each case determined by the glass giving the most distinct vision at twenty feet, with good and uniform illumination, usually controlled by ophthalmoscopic and keroscopic tests.

This method of observation was chosen as being, on the whole, with intelligent patients, less open to objections than any other, the possibility of the physician's bias being likely to invite criticism in ophthalmoscopic and other objective tests.

This report covers twenty-five consecutive cases tested in this way—all that time and opportunity permitted in the time included. The writer is not unmindful that similar experiments have been made and reported, but not in sufficient numbers nor with sufficient exactness and detail to carry conviction to the majority of ophthalmologists.

The effects produced by homatropia in these experiments have been a surprise to the experimenter, as they were not expected.

In the table of cases presented, the following points are noted: 1. Number in the series; 2.

Age; 3. Sex; 4. Condition for which relief is sought; 5. Vision of each eye; 6. Apparent refraction; 7. Date of use of homatropia; 8. Refraction exhibited under homatropia; 9. Remarks, noted at the time of making examination under homatropia; 10. Time of use of atropia; 11. Refraction under atropia; 12. Subsequent use of atropia, and remarks on the case; 13. Final vision.

ANALYSIS.

For purposes of comparison, the cases are divided into four groups:

1. Those in which there was no difference in the effect produced by homatropia and atropia, fourteen cases, or 56 per cent., viz.: Nos. 2, 3, 8, 9, 10, 11, 12, 14, 16, 17, 19, 21, 22 and 24. Of these, circumstances did not permit observations after the use of atropia longer than twenty-four hours in cases 3, 9, 10 and 11.

2. Those in which the use of atropia for twenty-four hours showed a diminution of refraction, without further change by longer continuance of atropia, two cases, or 8 per cent., viz.: No. 4, which developed 0.25 D. additional Ha. and No.

TABLE OF CASES.

Remarks.	Atropia Used.	Refraction under Atropia.		Remarks.	Final Vision.

.....	Apr. 19, 20.	No change.	No change.	January 11, no change.	$\frac{2.0}{2.0}$	$\frac{2.0}{2.0}$
				March 23, no change.	$\frac{2.0}{2.0}$	$\frac{2.0}{2.0}$
				March 23, no change.	$\frac{2.0}{2.0}$	$\frac{2.0}{2.0}$
				April 25, H. 6. April 30, same.	$\frac{2.0}{2.5}$	$\frac{2.0}{2.5}$

15, in which 4.50 DH. was changed to 5 DH. in one eye.

3. Those in which the use of atropia for twenty-four hours showed no change from the relaxation produced by homatropia, but in which change developed by longer use of atropia, three cases, or 12 per cent., viz.: Nos. 1, 18 and 25.

4. Those in which there was change from homatropia to atropia used twenty-four hours, but in which there was additional change by longer use of atropia, four cases, or 16 per cent., viz.: Nos. 5, 6, 7 and 21.

Cases 13 and 23 do not come under either of these heads. In 13 it was obvious at the examination that homatropia was insufficient.

The patient, however, did not return for four days, using atropia all this time, when accommodation was entirely relaxed, making manifest 0.75 D. additional H. In 23, while astigmatism was evident at the first examination, no cylinder was found that materially improved vision, this being but $\frac{2.0}{1.0}$. Atropia was used two days before the patient returned, when 1.25 D. Ha. was found, in addition to the 6 D. previously noted.

Atropia being employed immediately after

homatropia in these cases, may have given the former of an advantage.

It would be interesting to study the effect of homatropia after twenty-four hours' use of atropia; the effect of homatropia on several successive days, etc.

This is not a sufficient number from which to draw definite conclusions or generalizations, and none are attempted.

They are given as statements of fact in the hope that others will continue the observations, and that in this way such data will be presented as shall definitely settle the place of homatropia.

MALNUTRITION is the key-note to many disorders of childhood. Not only such obvious forms of malnutrition as the marasmus of diarrhoea, and the wasting of phthisis, should be noted, but also rickets in its frequently overlooked incipient forms, scurvy, and a host of troubles characterized by anæmia, flabbiness, inactivity, chorea, sweating and other neuroses should receive attention. Most of these yield to proper dietetic measures.

FIBRO-SARCOMA OF THE NECK WITH TEMPORARY OPHTHALMOPLÉGIA EXTERNA AND SYMPATHETIC PARALYSIS.

Read before the Section of Ophthalmology of the American Medical Association, at its Meeting in Washington, D. C., May, 1891.

BY H. V. WÜRDEMAN, M.D.,
OF MILWAUKEE, WIS.

J. F., aged 14, a student in the gymnasium of one of the theological schools in Milwaukee, a minister's son, German parentage, referred to me by Dr. D. J. Hayes, consulted me about a protrusion of the eyeball and double vision. The cervical lymphatics of the left side began to enlarge about eight months before and the swelling increased rapidly until at present it is the size of a large orange. There has been no particular pain or illness until a few days before, when Dr. Hayes was called to examine and prescribe for him on account of ill defined symptoms, among them headache and general malaise. The doctor kindly referred the case to me for treatment of the eye. The patient had been seeing double for several days and the eyes were observed to diverge since three days ago.

Upon examination I found a large nodulated tumor of the left cervical region which had pushed the trachea to one side. The left side of the face was flushed and seemed warmer than the right. Complete ptosis existed, the lid falling to lower edge of the pupil, which was contracted and did not respond to light or shade. The eyeball was directed downwards and outwards and away from the median line, making an external squint of about 35° . The conjunctival vessels were flushed. Ophthalmoscopic examination showed the veins more tortuous and fuller than on the papilla of the other side. The tension was slightly lowered, being T. — 1. The accommodation seemed partially affected, the near point being at 75 cm. while that of the other eye was 12 cm. V. R. E. $\frac{6}{8}$; V. L. E. $\frac{6}{12}$. Examination of the refraction showed him about one diopter hyperopic in both eyes. He complained of a dull continuous headache and seemed stupid. Through the kindness of Dr. S. F. French, who took the excellent photograph I present, I am enabled to show the general appearance of the patient upon the day of the first examination.

The eye was bandaged and the patient directed to take hot baths and rest. To my surprise in four days the squint was lessened to about 20° , the eyeball was less prominent and he could raise the lid above the level of the pupil with an effort. The pupil was still contracted and could only be partially enlarged by homatropin. The fundus appeared about the same and the accommodation seemed likewise. The temperature of the affected side was yet warmer to the touch and more flushed than the other. He said that the head-

ache did not trouble him as much, and in the examination he seemed less confused. In one week from the time that I first saw the case the eyes were straight, although double images could still be elicited. I had examined the patient on several occasions, on each of which no trouble of the accommodation could be found. The pupil was still more contracted than that of the other side. V. R. E. $\frac{6}{8}$; V. L. E. $\frac{6}{8}$. Tension normal. The temperature of both sides seemed the same. The tumor appeared larger but softer.

About this date Dr. Hayes injected a portion of the growth with cocaine and removed a little for microscopic examination. Dr. H. V. Ogden made the sections and reported that the sample showed scattered sarcomatous elements with fibrous tissue in preponderance. Several days later the largest nodule of the growth being very soft was opened and removed.

I had hoped to give a photo-micrograph of the section, but I am informed that the specimen has been lost. I saw the patient a month afterwards when he had binocular vision and the eye appeared normal with the exception of slight myosis and ptosis. The pupil responded slowly to light. As an operation on such a large growth, involving such important structures, was not deemed advisable, the boy was sent to his home in the country. His father wrote to Dr. Hayes some six weeks later that the eye remained in about the same condition as last stated. The tumor of the neck was slightly larger and firmer and the sinus was healed. At present writing, nine months from date of first examination, the boy is yet alive. The tumor has broken down in places and discharges through several sinuses.

It seems to me that the eye symptoms were

not incidental, but directly attributable to the pressure of the cervical growth upon the sympathetic nerve. The boy had suffered no exposure previous to the ocular affection and was carefully watched during its course.

There was no co-existing catarrhal disease or any other symptom that might lead one to suspect that the trouble was due to cold. I trace the progress of the disease in the following way: The cervical growth produced an interference of the functions and finally paresis of the sympathetic through pressure upon its trunk. This was the cause of the myosis and of part of the ptosis, the former being due to paralysis of the radiating muscular fibres of the iris, which are under the control of the sympathetic,¹ and the latter to the implication of the M. Palpebralis Superior, or Müller's muscle, which is innervated from the same source.² The reduced tension was likewise due to the sympathetic lesion.³ The one-sided increase of temperature also upholds this view of the subject. All of these symptoms have been described by Horner⁴ as indicative of lesion of the cervical sympathetic, and have occurred in cases where the trouble was clearly due to the pressure of enlarged cervical glands or other tumors upon the nerve trunk in this region.

Section of the sympathetic in the neck or inhibition of its function produces a very great increase in the supply of blood to the side of the head corresponding to the section or lesion.⁵ The increased temperature is due to a local exaggeration of the nutritive processes depending upon the hyperæmia. That the cerebral circulation was affected is evinced by the dull headache and general stupid condition of the patient at the time of examination. Hyperæmia of the brain and its membranes is given by several authorities⁶ as a cause of ocular paralysis. I am reasonably certain that the supposed inhibition of accommodation was due to the stupidity of the patient at the subjective examination, and therefore this factor may be excluded. The muscles of the eyes involved were the external, with the exception as above noted. The implication of these muscles was due to some disturbance in the function of the oculomotorious center under the Sylvian aqueduct, due to the hyperæmia induced by the sympathetic lesion in the neck.

A lesion of the nucleus is an usual cause of external ophthalmoplegia.⁷ As soon as the condition of the blood vessels in this locality became restored to the normal state of affairs its function was renewed and the muscles came under control of the nerve center. The same thing happened to the sympathetic itself, although the paresis

was not so evanescent, as its peripheral effects were observable at the last examination some four weeks from the first time that I saw him, and and were, in all probability, the eye symptoms referred to in the letter mentioned.

ANALYSIS OF THE SENSORY CHANGES AND CONDITIONS OF THE OCULAR APPARATUS AS FOUND IN IMBECILITY, EPILEPSY, AND GENERAL PARALYSIS OF THE INSANE.

Read by title in the Section of Ophthalmology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY CHARLES A. OLIVER, M.D.,

ATTENDING SURGEON TO WILLS' EYE HOSPITAL, ETC., PHILADELPHIA.

The present paper¹ is based upon a series of observations the result of five years' work at the State Hospital for the Insane at Norristown, Pa. The special character of research treated of in this communication, which has been carefully pursued by the aid of competent assistants, is here given as a series of concluding remarks upon those symptoms which have been deemed sufficiently proper for generalization and conclusion. It must be remembered, however, that the work as at present given cannot be considered complete, even from a clinical standpoint, because in reality it consists in a mere placing of all of the more certain sensory changes found in the three conditions (and before published in a separated form), into a single and combined grouping, thus hoping, as was attempted with the motor symptoms, to place them side by side for comparative study. Not that the results can be considered absolutely conclusive; not that there may not be many discrepancies, both from lack of instrumental precision and the difficulty to obtain definite data in each instance, yet still as they show in brief a concise resumé of the practical work which has been going on in the Ophthalmological Department of the Institution for a sufficient length of time to draw probably some useful conclusions, it is here given in the hope that their embodiments, even though tentative, may be of sufficient interest to excite further study in these directions.

As the real subject matter of the paper has reduced to a series of short observations bearing directly upon the different conditions found, taken

⁷ Fuchs, p. 606.

¹ This paper, which practically presents an epitome of the sensory peculiarities seen in these clinical groupings, terminates a series of studies which have been written upon by the writer from time to time during the past four years, and which have been more or less confirmed by later investigation. The first article appeared in the *Philadelphia Medical Times* for Feb. 5, 1887; the second was read before the American Ophthalmological Society in July of 1887; the third and fourth were read before the same body two and three years later; whilst the fifth, which contained the final report upon the motor symptoms, was published in the *American Journal of the Medical Sciences* for November of that year.

from the original papers, and as the results have been made into several concise groupings, it will be necessary in such a paper as this to repeat the circumstances under which the studies were made, and to give a brief account of the precautions taken to obtain as near perfect material as possible. To do this, the writer can do no better than to refer to the following abstracts taken from an earlier paper² upon the other branch of the subject:

"1. A special variety of symptomatic disease was taken in preference to any mental condition, because similar mental states in the many and bizarre forms of nerve lesions, making and hiding the true significance of the objective symptoms peculiar to any one disease to such an extent as to render differentiation impossible, are very frequent in mental disorders.

"2. A definite variety of disease was chosen, so as to avoid obtaining a mere percentage of the ophthalmic signs of the total number of cases occurring in one asylum, an answer which through constant changes in the number of the resident population, or temporary peculiarities in the character of mentality, is liable to alter at any time, and thus make such an analysis give results and conclusions which would be totally diverse from those that might be obtained by another observer placed in a different situation.

"3. A large percentage of similar cases was taken. This was done, so that the different mental states which are seen during a definite situation in the course of any one disease might be united in a theoretical example of the physical and physiological conditions of the disease at that stage.

"5. Males were used; this is important, for, by the exclusion of the female subject, any errors that might arise from additional ocular changes dependent upon diseases which are peculiar to the sex, would thus be avoided."

At first, among the epileptics, no differential diagnoses were attempted as to the causation of the convulsions, this being done so as to embrace the entire grouping of such cases into a common lot of subjects, in order to have the greatest variations of supposable differences present at one and the same time, and thus to give greater latitude to error. Later, however, as the subject became more familiar and finer differentiations became more visible, attempts were made to isolate the cases into specialized groupings.

During the examination of the imbeciles, the following precautions were observed:³

"1st. Care was taken to exclude all but the proper class of subjects, no one being admitted who could not be properly designated as one with decided loss of mental power of a minor degree

than idiocy, from malformation or disease of the nervous system, either supervening in infancy or occurring before birth. This was done so as to avoid any error that might arise from the presence of ocular symptoms which might be dependent upon other malformation or disease, and to exclude any question as to the use of the eyes for prolonged near-work during the early years of life.

"2d. Subjects chosen whose eyes were free from extraneous disease or inflammation. Sore eyes of inflammatory and traumatic types were avoided, so as to obtain as nearly as possible representative peripheral (end) organs of comparatively healthy functional activity.

"3d. Young adults were used. This was done for two reasons: first, to have the eye at its full maturity, and thus not to allow any question of further development to enter into the argument; and, second, to have the tissues of the eye at their best before any of the processes of natural decay should have manifestly asserted themselves.

"4th. Males have been taken. These were chosen so as to avoid any errors that might arise from additional ocular changes which might be associated with diseases peculiar to the female sex.

"5th. Every subject was submitted to the same routine examination, thus preventing any seemingly gross changes to appear that might arise from differences in methods of study.

"The reasons for such rules must be obvious, as by their observance all faults in working and want of precision in method are reduced to a minimum, and the conclusions, which are the very import of the work, are thus rendered more valuable and less liable to grave and deceptive error.

"In the third series of cases great care was exercised that each subject was seemingly free from any extraneous general disease or local disorder, and that competent and authoritative medical opinion had been given as to the type of the general complaint; besides, the entire study in this direction has been limited to the male sex, so as to escape any conflicting complicating changes that might appear in connection with the many diseases peculiar to the female sex."

OBSERVATIONS—EPILEPSY.

Subjective.

1. Direct vision for form as a rule normal in both emmetropia and corrected ametropia.

2. Direct vision for color slightly subnormal as shown by faulty selection of delicate tints and shades containing low percentages of green and red.

3. Visual fields for both form and color regularly reduced, without either transposition or reversion.

²American Journal of the Medical Sciences, Nov., 1890.

³See Transactions of the American Ophthalmological Society, 1887.

Objective.

4. Optic disc superficially overcapillary, the deeper layers being decidedly gray, showing a low grade of incipient optic nerve degeneration; this being more marked in the cases where the general convulsive seizures were the most frequent.

5. Scleral ring rather more sharply cut than in the healthy eye, especially to the temporal side of the disc; this being probably due to shrinkage of lowered nerve tissue.

6. Fibre-layer of retina increased in thickness, as shown by coarse and dense massings of striation which extend in all directions from the disc; these being the most pronounced superiorly and inferiorly.

7. Retinal vessels, especially the veins, large in size, and carrying rather dark colored blood.

8. Retinal veins very tortuous, and at times pulsating.

9. Retinal arteries frequently wavy, and sometimes tortuous, particularly the temporal and the macular twigs.

10. Retinal lymph channels generally visible, being recognized as glittering and yellowish-white opacities along the larger vessels and at the vessel entrance on the disc.

11. Granular condition of choroid in the macular region, this being found in the majority of cases.

IMBECILITY.

Subjective.

12. Direct vision for form, as a rule, normal.

13. Direct vision for color probably normal.

Objective.

14. Optic disc 'apparently more healthy than would be expected for age of patient.

15. Physiological excavation generally seen, usually small, shallow, oval in outline (its long axis bearing no definite relation to the long axis of the disc), and ordinarily occupying a position slightly to the temporal side of the centre of the disc.

16. Scleral ring, as a rule, visible all around disc, it being slightly broader to the outer side.

17. Pigment massings beyond scleral ring ordinarily limited to narrow concentric splotchings and double loops, which are more pronounced to the nasal and temporal border of the disc; the outer massings being generally crescentic.

18. Entire absence of so-called conus. In no instance could a broad crescentic area of bared sclera be distinctly seen; the temporal massings in those eyes which were presumably used the most being roughened and broken on their outer edge, and connected with small and narrow areas of disturbed retina and choroid.

19. Fibre layer of the retina but very slightly increased in thickness; the fine and oftentimes im-

perceptible striation being almost entirely limited to the superior and inferior portions of the nerve border, and extending but a short distance out into the retinal plane.

20. Lymph reflexes and opacities of the vascular sheaths very few, these being mostly confined to the main venous stems at their exit on the disc.

21. Retinal vessels about normal in comparative size, and in a few instances carrying impoverished blood.

22. Choroid devoid of change, except a somewhat granular condition, more pronounced in the macular region; this sometimes being accompanied by a slight absorption of epithelium (especially amongst the most intelligent).

23. Entire absence of any gross congenital malformation.

24. Almost equal degrees of hypermetropia with slight amount of astigmatism present in every case, the average amount of H. being about 2 dioptries.

25. The less imbecile the subject, the more common were the ordinary conditions seen in the used eyes of the mentally healthy.

GENERAL PARALYSIS OF THE INSANE.

Subjective.

26. Direct vision for form reduced in every instance where obtainable; this being in direct ratio, where there was any degree of certainty, to the stage of the disease.

27. Direct vision for color subnormal in the few instances in which it could be properly studied; this showing itself more particularly for green and red.

28. Visual fields more or less reduced in the few cases where any determinate answers could be obtained.

Objective.

29. Optic discs decidedly and unequally semi-atrophic, especially in the later stages of the disease; the degeneration being especially pronounced in the deeper layers and to the temporal side of the nerve head.

30. Capillarity of nerve substance materially lessened, the greatest amount of blood supply being recognized in rather narrow crescentic areas to the nasal side of the disc.

31. The disc, in a few cases seen in the third stage of the disease, of a suffused and gelatinous appearance, its edges being plainly visible, and the surrounding retina being somewhat cedematous.

32. Physiological excavation frequent, it usually being seen to the temporal side of the disc, and extending to the lamina.

33. Scleral ring sharply cut and, as a rule, broad; this being more noticeable to the temporal side of the optic nerve head.

34. Blackish crescents of pigment, broken and

more or less absorbed beyond the scleral ring, frequent at the outer edge of the disc.

35. Pigment lines of different widths and varying degrees of absorption beyond the scleral ring, at the inner edge of the optic nerve head.

36. Fibre layers of the retina, as a rule, diminished in thickness, the greatest amount of striation being seen at the superior and inferior borders of the optic disc.

37. Retinal striation, in a few instances seen during the third stage of the disease, very pronounced, rendering the disc edges quite hazy.

38. Retinal arteries reduced in size, and at times slightly tortuous.

39. Retinal veins, as a rule, undersized, tapering in some instances as they enter the disc, and quite tortuous in a number of cases.

40. Retinal blood currents apparently normal in tint.

41. Retinal lymph reflexes very few; these being generally limited to the walls of the main vascular stems.

42. Fine pin-point opacities in the retina, between the disc and the macula, in a few cases.

43. Choroid granular and disturbed in the majority of cases.

CONCLUSIONS.

1. In idiopathic epilepsy as seen in the male adult, the low grade chronic retinitis and perivascularitis associated with partial red-gray degeneration of the optic nerve, causing decrease of physiological working power, are most probably explained in part by the presumption that every convulsive discharge leaves an additional pathological condition, by which such objective intra-ocular appearances are at last established, as the visible living results of a similar process which has *pari passu* been taking place within the intracranial substance, especially the cerebral cortex, and which may be readily seen post-mortem by careful microscopic examination.

2. In the lower grades of imbecility as seen in the male adult, which have resulted from malformation, or from disease of a minor degree than that producing so-called idiocy, that has supervened in infancy or has occurred before birth, the ophthalmoscopic findings of abnormally healthy eye-grounds, presenting pictures that are almost identical with those seen during infantile existence, indicate not only an almost absolute perfection of the visible constituents of the observed tissues, which *per se* should be capable of proper functional activity, but plainly show, by reason of mental incapacity which has supervened in such subjects before the eyes have been brought into continued and constant action as instruments of accurate and delicate use, that the ordinary objective conditions known as: dirty red-gray appearance of the optic disc; irregularity of physiological excavation; non-visibility of the

superior and of the inferior portions of the scleral ring; absorbing conuses in all of their varieties; increase in density and thickness of the retinal fibres; opacities of vascular lymph sheaths; disturbed states of the choroid; and gross errors in astigmatism, with changes in indices of refraction—which are so frequent in the used eye of the mentally healthy—must be considered as pathological changes expressive of low inflammatory action, with stretching and distortion from increased intra-ocular and extra-ocular pressure.

3. In general paralysis of the insane as seen in the male, the ophthalmoscopic appearances of the choroid, optic nerve and retina, are not only indicative of pronounced local disturbance and irritation which represent the results of wear and tear given to a delicate and greatly weakened organ, but are plainly expressive of a degenerate condition of the sensory portion of the ocular apparatus, with impairment of sensory nerve action, manifested as one of the many peripheral evidences of fast approaching degeneration and dissolution of nerve elements, most probably connected with related cortex disintegration and tissue death.

SUBGLOTTIC NEOPLASMS.

Read in the Section of Laryngology and Otology, at the Forty-second Annual Meeting of the American Medical Association, Washington, D. C.

BY JONATHAN WRIGHT, M.D.

OF NEW YORK.

From clinical experience in hospital and private practice in diseases of the nose and throat, including a large number of cases, it seems evident to me that disease of the larynx and trachea of any description is not so frequently met with in New York, as the records of foreign, especially German and French, experience would lead us to believe. Neoplasms of the larynx are certainly not as frequently met with, either benign or malignant, as they are in Europe, or else they are given an undue prominence in foreign literature. While it may be true that benign laryngeal neoplasms exist in the proportion of 1 to $\frac{1}{2}$ percent. of all laryngeal cases in this country, laryngeal affections in general are much less common than abroad. This personal opinion may not be sustained by the experience of other Americans, but there is reason to believe that I am not alone in the observation.

Various localities in the air passages have been mentioned as the most common situation of benign growths, but a careful perusal of literature will, I think, show, notwithstanding considerable discrepancies of statement, that the most common place of development is on the vocal cords or at either commissure. It is conceded that their etiology depends largely upon irritation. Such being the case the places where we should naturally expect to find them would be the most

mobile parts of the larynx and those parts most exposed to the irritation of air, dust and secretions. The subglottic space being the most protected and the most immobile part we should expect less morbid action there. This conforms to clinical observation. Of 1,100 cases, collected by von Bruns, of laryngeal neoplasms, 836 were on the vocal cords. Subglottic tumors are, however, of great rarity, nine only of Fauvel's 300 cases being infra-glottic.

The following history of a case which has lately come under my observation may not be lacking in interest and may at least illustrate some important points to remember in connection with subglottic growths.

M. C., a housemaid, æt. 20. Single; born in Hungary, came to the Demilt Dispensary in May 1890. Her family history was good. Three years ago she had been troubled with frontal headaches and pains in the bones which were worse at night. At that time she began to have a hoarse cough and some muco-purulent expectoration. Her nose was stopped up and she picked it making it sore inside. These symptoms increased. For the last year she had gradually been growing short of breath on exertion, having, however, no difficulty while quiet except at times on severe coughing, of which she had several attacks each day. At times for the last year she had noticed some huskiness of the voice, but as a rule there had been no marked change in it. For the last three weeks she had been feeling weak and unfit for work. Specific history was denied.

Examination.—Pulse and temperature were normal. Respiration 24. She had slight stridor but no dyspnoea.

There was some enlargement of the cervical glands but no other evidence of specific disease.

On the left side of the nasal septum in front there was a papillary growth extending over the floor of the nose and to some extent over the anterior end of the inferior turbinated bone. It was covered with inspissated bloody mucus. There was marked thickening of the mucous membrane in the right nostril. The posterior border of the Vomer had also several wart-like growths, especially where it joins the base of the skull. There were two or three about the size of barley grains on the posterior surface of the soft palate.

Below the vocal cords there was a large congested looking mass which at first glance seemed to block the whole lumen of the trachea. During the greatest possible abduction of the vocal cords, however, it was seen that the base of the growth was attached to the left side of the cricoid cartilage and the tracheal rings, and projected to the other side beyond, but considerably below the edge of the right vocal cord during quiescence. The surface looked uneven, covered with mucus, and as though it were very vascular (this proved

otherwise however). The mucous membrane on the right side of the subglottic space was also seen to be thickened and roughened.

Her imminent danger was explained to the patient, who was somewhat incredulous, but who nevertheless promptly consented to enter the wards of Roosevelt Hospital.

For diagnostic purposes iodide of potash was given in increasing doses. After a few days signs of iodism appeared and the patient had suddenly almost fatal dyspnoea. A tracheotomy was done just below the cricoid cartilage, artificial respiration resorted to and the patient recovered.

Four days later, Dr. Frank Hartley made a long incision dividing the thyroid cartilage and several rings of the trachea, exposing the interior and the growth, which proved to extend downward for about $2\frac{1}{2}$ inches below the vocal cords and to involve $\frac{3}{4}$ of the circumference of the trachea at the point of greatest growth. It had all the macroscopic appearance of an ordinary papilloma. As soon as the trachea was opened the patient ceased breathing and it required energetic artificial respiration and hypodermic stimulation to start the natural respiration again. It was found impossible to resume the ether, although several attempts were made causing cessation of the breathing. Of course etherization was commenced through the tracheotomy tube and later given through a tube inserted at the lower angle of the tracheal wound. The operation was therefore finished under partial anaesthesia. The growth was found to be flattened by the pressure of the tracheotomy tube. It was cut away from its attachment, which included the under surface of the left vocal cord, by knife and scissors, the base and every vestige of suspicious looking mucous membrane, including the small growths on the right side, were thoroughly and deeply cauterized with the Paquelin cautery.

A tracheotomy tube was left at the lower angle of the wound, and the upper part of the trachea and the larynx was packed with iodoform gauze. The latter was removed in a few days and some weeks later the tube was withdrawn and the wound closed without any untoward symptoms, but she remained totally aphonic.

She was discharged from the hospital and again became an out-patient under my care. The growths were removed from her nose by cautery, snare, and forceps.

At the anterior laryngeal commissure was a pale, flabby growth about the size of a split pea. It was apparently a granulation nodule at the site of the thyrotomy incision. Failing with the forceps, this was destroyed by the galvano-cautery.

The patient was kept under occasional observation for six or seven months. Her voice did not return, but at the end of that time small sessile growths began to appear just beneath the

right vocal cord. A small portion of these was removed with the laryngeal forceps. Since then the patient has disappeared from view. There was no deterioration of the general health, although the patient naturally became somewhat hypochondriacal. The left vocal cord in the process of cicatrization was almost completely destroyed, at least as far as its usefulness in phonation was concerned.

Gerhardt has lately stated that the differential diagnostic point between syphilis of the trachea and tracheal cancer is that cough and signs of irritation do not occur in cancer as initial symptoms, dyspnoea being the first sign of trouble. In this case, which, however, was a benign tumor, it will be noted that a harsh cough preceded the dyspnoea by two years.

In fact, it is remarkable how little dyspnoea the patient suffered when her trachea was all but occluded by the growth. It was only on exertion, or from some temporary increase of mucus or transient congestion from coughing, that she experienced much discomfort. Such cases show how much larger than necessary for quiet respiration the trachea is, the extra size being Nature's supplementary device for emergencies—a device which makes violent and extraordinary exertion possible, and which renders simple inflammatory inflammations all but harmless.

It illustrates a point too often forgotten in obstruction of the air passages, viz., that the dyspnoea is most frequently due not so much to the mechanical stenosis as to the spasmodic or paralytic condition of the vocal cords, which irritation of the mucous membrane or compression or irritation of the nerve trunks may cause.

Intrinsic *laryngeal* tumors and extrinsic tumors pressing on the air passages, close alongside of which run the nerve filaments, may cause severe attacks of spasmodic dyspnoea, whatever the size or extent of the disease may be, while intratracheal disease rarely gives any dyspnoeic symptoms until the mechanical stenosis is very great.

Koch,¹ in his late article, said:

"If a tracheal tumor produces dyspnoea, that tumor is necessarily of large size, and of such a nature as to suffocate the patient at any moment. The laryngoscope gives us a defective idea of the size of the tumor on account of the inevitable shortening of the vertical diameter, while the intensity of the dyspnoea furnishes us with a more exact guide."

How suddenly, and with what little premonitory warning, an almost entire occlusion of the remaining air chink may take place, and the patient pass from comparative comfort into a condition rapidly terminating in suffocation is shown in this case, and in others of a similar nature. In dyspnoea caused by spasmodic contraction of

the vocal cords—the dyspnoea of many cases of thoracic aneurism, of hysteria, of inflammation, of *laryngeal* neoplasms—there is usually a certain leeway allowed for the performance of tracheotomy, because, as soon as insensibility from the carbonic acid poisoning occurs, the spasmodic action of the glottis is usually suspended, though this is not inevitably the case. The sufferer may then gradually return to consciousness, or at least get enough air to keep his heart going for a time. Purely mechanical obstruction, however, is a different matter.

Therefore, when the iodides are given for obstructive disease of the air-passages which may not be syphilitic, and even in cases where the diagnosis of specific disease is certain, especially when the obstruction is subglottic, it is well to remember that *slight* congestion is a very common sequel of even moderate doses, and that even slight congestion may prove disastrous if immediate surgical aid is not at hand.

More than half of all the cases of benign laryngeal neoplasms reported have been recorded as papillomata. It is very suggestive of insufficient pathological discrimination that there should be such a preponderance of this growth. As to the character of the growth in the case reported, you will see from a drawing of a microscopic section made by Dr. Hodenpyl that it consists essentially of a mass of lymphoid tissue covered by pavement epithelium, which dips down into its substance as digitations, and rises above the surface as papillae. These papillae, as well as the substance of the growth, have for a framework the masses of lymphoid cells. There was more than the usual amount of fibrous tissue found in the ordinary so called adenoid growths, though in the section from which this drawing is made it is not apparent.

If we regard this as a true tumor, the proper designation, according to the rules laid down by Virchow, would be "Lymphoma papillare." If, however, we are to accept the definition of a tumor, "that it is a non-inflammatory growth or new formation of tissue fulfilling no physiological purpose," this, as well as all so-called adenoid vegetations, should be designated as a papillary lymphoid hypertrophy. This is a question for histologists who are accustomed to arrange such matters to suit themselves, irrespective of clinical convenience and experience.

Lymphoma of the larynx, according to all authorities who mention it, is of the greatest rarity, as are many of the other benign forms of tumors, although they are common enough on other mucous membranes. This is probably due to the fact that in the larynx, as is the case in the bladder, morbid growths, either benign or malignant, are usually attended with the increase and hypertrophy, as well as the new formation of papillae, on their surfaces.

¹Koch: Ann. des mal de l'oreille, etc. Oct., 1890.

Notwithstanding the protest of Virchow, and of many of the best histologists, these growths, when benign, are all classed under the head of "papillomata," whatever may be the predominant histological element in their structure.

This leads to great clinical confusion, and to a mistaken conception of the nature and pathogenesis of these growths.

The only records of so-called lymphoma of the larynx which I have met with are two cases, one referred to by Gottstein in his book, and another reported in the *Lancet* for October 15, 1887, by Beale; both of these accompanied general lymphomatosis. Wolfenden and Martin however, in their brochure, "Studies in Pathological Anatomy," give a drawing of lymphoid hypertrophy, which they call lymphoma, and which occurred in the larynx independent of any general affection.

Notwithstanding this apparent rarity, I do not believe it can be so uncommon, but that some of these papillary tumors, if carefully examined, would be found to consist largely of lymphoid tissue. Sarcoma is also extremely rare in the trachea.

Such mistakes in nomenclature have been largely avoided in malignant tumors, owing to the importance of the prognostic aspects in such cases; but malignant tumors of the mucous membranes are quite as likely to be supplied with fungous or papillary surfaces as are benign growths, if not more so.

As observed above, it is rare that small tracheal growths come under observation, except where they coexist in the larynx. The question of treatment is in these cases frequently a puzzling one, and always an important consideration.

Those rare forms of tracheal gummata occasionally seen are of course to be treated by large doses of iodide of potash, and it may always be advisable, with proper precautions, to give the iodides where the diagnosis is not perfectly plain.

Leaving malignant tumors out of the question, and confining ourselves to the class of cases of which the one reported is a type, there are three methods of extirpation where interference is advisable :

1. Intubation with long O'Dwyer tubes.
2. Intra-laryngeal operations; by
 - a. Forceps or snare.
 - b. Cautey, either galvanic or chemical.
3. Extra-laryngeal operation.

The procedure by means of intubation is yet in its infancy, and is, of course, applicable only to those subglottic cases where the disease lies close beneath the vocal cords. Rapid absorption of benign and even syphilitic growths have been reported by Simpson and others. Intubation can probably be advantageously employed in connection with the intra-laryngeal use of the forceps

or of the cautery. With this I have had no personal experience, but it is certainly deserving of a trial, the dangers and difficulties which attend other methods being absent or reduced to a minimum by intubation, and in event of failure, the toleration acquired from the intermittent use of a tube would be of the greatest advantage in intra laryngeal operations.

The greatest difference of opinion prevails as to the proper cases for intra- and extra-laryngeal operations, some going so far as to urge an external operation even in supra-glottic tumors in adults, while others go to the other extreme by urging that even in children infra-glottic growths may be removed *per vias naturales*, cases having been reported where papillomata were removed from the fifth tracheal ring. The sanction of Fraenkel, of Berlin, to intra-laryngeal operations in cancer will not now be received with favor by the majority of laryngologists.

In tracheal growths, in the vast majority of cases, the tumor will usually be of such a size when first seen that nothing but an external operation would be advisable. In small, benign growths, in a tolerant adult, attempts by the intra laryngeal method will often be met by the most brilliant immediate results even in the trachea, but recurrence will be frequent, because it is impossible to be sure that the growth is completely eradicated.

Where attempts are to be made in larger tracheal growths, through the natural passages, thorough preparation both of patient and attendants should be also made for an immediate external operation, because, in event of failure to remove the growth, enough congestion and inflammatory action may be set up to lead to complete tracheal occlusion.

The choice of instruments will depend largely on the personal bias and skill of the operator and the character of the growth. Personally, for small sessile growths, I prefer the white hot guarded galvanic-cautery electrode. For growths which project more onto the lumen of the trachea, McKenzie's lateral or longitudinal forceps are preferable, with, however, more of a gradual curve at the angle than is seen in the usual patterns.

Canterization by chromic acid, although recommended by some of the most experienced operators, seems to me of inferior value, except to cauterize the base of a tumor removed by the forceps. When the epithelium is intact, these growths certainly are not as quickly destroyed by acids as by the actual cautery. (Of course, I speak principally from experience in other situations than the trachea.)

A very practical point in these intra-laryngeal operations is the way in which the patient reacts to the application of cocaine. In many patients it leaves nothing in the way of local anæsthesia

to be desired. In others it seems impossible to produce satisfactory results with any safe dosage, this applying to the 20 per cent. strength as well as to weaker solutions. Cases are not rare where severe constitutional symptoms of the drug may appear before any practical local action is observed. It is at once the most useful and the most uncertain of drugs.

In considering the question of an external operation, the operator should be well satisfied of the impracticability of the operation by the natural passages. In many cases a preliminary attempt may be made by intra-laryngeal methods, and in event of failure, the external operation immediately done.

The dangers of the external operation are not only that to life, but also to the integrity of the voice. It is unnecessary to dilate upon the dangers of fatal pneumonia or bronchitis following the operation. This case illustrates a danger which is not satisfactorily explained, namely, the occasional prompt cessation of respiration or of the heart's action the moment the trachea is opened. I have had two cases of tracheotomy where the heart was paralyzed at the moment of opening the trachea, although the pulse had been a moment before fairly good. There seems good grounds for the belief that there exist areas below the glottis, the excitation of which may profoundly affect the functions of the heart and lungs. It is possible that these areas may also exist outside of the trachea in the anterior cervical region. At any rate, there are enough cases on record to demonstrate that this operation has dangers beyond those usually ascribed to it.

In tracheal tumors there is the added danger of hæmorrhage from an incision of the tumor itself in opening the trachea. When a vascular tumor is attached to the anterior wall, this may cause very great embarrassment to the operator, and a fatal termination may ensue.

The danger to the integrity of the voice is of course not to be weighed in the balance with the patient's life, and should be entirely a secondary consideration. It is probable that the early writers have exaggerated this danger even in laryngeal growths. The simple separation one from another of the wings of the thyroid cartilage, bearing with them the attachments of the vocal cords, is probably a minor factor in the production of future aphonia or dysphonia. The danger comes from damage to the vocal cords themselves, and this may occur in endo-laryngeal operations as well. In the eradication of tracheal growths by an external operation, the division of the thyroid cartilage will usually be found necessary to gain room, and should not be omitted for fear of damage to the vocal apparatus.

A preliminary low tracheotomy is not a necessity, nor always of advantage, in spite of what

Koch says at the end of his article, although in some cases it may facilitate matters. It would be encroaching on the domain of general surgery to go further into the question of the technique of an external operation for these tracheal growths, suffice it to say that the indication is usually perfectly plain, and should be promptly met, as every moment of delay is fraught with danger to the patient.

In sections made from the fragments removed from the recurrence on the right side of the subglottic space, the microscopic appearance had more the resemblance of a small, round-celled sarcoma.

The difficulty in distinguishing lymphoid growths of the mucous membrane from small-celled sarcoma by microscopic examination is often very great. In the last year I have been puzzled in several cases, and submitted the sections to several experienced microscopists. In every instance I met with a diversity of opinion as to the character of the growth.

I have a number of such sections in my possession, and the similarity between the simple lymphoid growths and those which afterward proved to be malignant is striking.

In one case, I followed by repeated microscopic examinations of fragments removed at different times the course of a small, round-celled sarcoma of the nose. The first specimen was universally regarded as of a benign lymphoid character. It gradually changed in appearance to that of undoubted sarcoma, of the small, round-celled variety. The clinical history and situation made the diagnosis of sarcoma probable, even at first.

EXCISION OF THE MEMBRANA TYMPANI, THE MALLEUS AND INCUS, AS A MEANS OF TREATMENT IN OTITIS MEDIA CATARRHALIS CHRONICA, AND IN OTITIS MEDIA PURULENTA CHRONICA.

Read in the Section of Laryngology and Otology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY CHARLES H. BURNETT, A.M., M.D.,
AURAL SURGEON, PRESBYTERIAN HOSPITAL, ETC., PHILADELPHIA.

That which is offered in this paper is somewhat of the nature of a report on the progress of aural surgery in a very important direction. Although not a new operation, the operation of excision of the membrana tympani and the two larger ossicula, as performed in this country, in thorough organization and elaboration, is new, and entirely due to the labors of Dr. Samuel Sexton, of New York. Excepting Dr. Sexton, Dr. Colles in New York, and myself in Philadelphia, are

the only ones in this country who have performed the operation and published accounts of its performance.

The indications for the operation are:

1. The deafness, tinnitus and vertigo of otitis media catarrhalis chronica, especially when adhesions exist between the membrana tympani and the promontory, or there is evidence of synechia between the ossicles.

2. The suppuration, deafness, tinnitus, vertigo, headache and recurring earache of otitis media purulenta chronica.

The *rationale* of the operation, in chronic catarrh of the middle ear, is the improvement of the hearing by obtaining a permanent perforation in the membrana tympani, and, by a removal of the malleus and incus, to unload the stapes, and thus relieve the tinnitus and vertigo so often found in this disease, usually mis-called Ménière's disease, and incorrectly referred to nervous disorder in the labyrinth. In otitis media purulenta chronica, by excision of necrotic tissue, drainage is improved, and more direct medication being applicable, the suppuration in the tympanum is checked. Cessation of the suppuration, reduction of the swelling of the mucous membrane about the fenestræ, and the removal of such mechanical obstructions, relieve deafness and tinnitus, and the stapes being thus unloaded, vertigo is checked. The operation, as performed by myself, has always been upon the etherized subject, the ear being illuminated by a 6 volt electric head-lamp, of two or three candle power, run by a 6-volt portable battery. The lamp is an Edison incandescent lamp, the illuminator or lantern holding it being made by the River and Rail Electric Light Company of New York, while the battery I now use is a 6-volt storage battery, weighing 11 lbs. 6 ozs., made for me by the Electro-Dynamic Company of Philadelphia. By this means a pure white light is obtained.

Anæsthesia is necessary, as the patient must be absolutely still. The use of ether, which I prefer, necessitates the employment of an electric lamp, to avoid the risk of setting the patient on fire, as an artificial light must be brought very near to insure sufficient illumination of the ear. Reflected sunlight would answer the same purpose, if it could always be had when and where desired. The electric head lamp gives direct illumination, which allows a freedom in the movements of the surgeon's head, greater than reflected light would permit.

The operation in otitis media catarrhalis chronica is necessarily different from the operation in otitis media purulenta chronica, as in the former the membrana tympani and ossicula are intact, while in the latter, parts of the auditory conductors have been destroyed by disease. The operation in chronic catarrh of the middle ear, as performed in this country, consists in making,

first, an initial incision behind the short process of the malleus, continuing it by means of a probe pointed knife up to the membrana flaccida and then backwards, throughout the periphery of the posterior superior quadrant of the membrana, so as to expose the incus-stapes joint. I do not cut into the bone tissue to do this. If the incus-stapes joint, which lies very high in the attic in some subjects, cannot be exposed by exsection of soft tissues, I proceed without touching it at this stage of the operation. When the incus-stapes joint is exposed, I pass between the malleus and incus a small two edged knife, triangular in shape, 2 mm long, set at right angles on a slender shaft, and rotate the instrument between thumb and forefinger and sever the incus-stapes joint. The surgeon's eye can easily follow all of this manœuvre. Now the incision in the membrana tympani may be carried a little lower, both on the periphery and manubrium, if the perforation is not already large enough to permit the withdrawal of the incus.

2. While the incus is held in position by its attachment to the malleus in front and by its short process behind, the long process may be seized with forceps, and the entire bonelet easily withdrawn. If this is not done at this stage of the operation, subsequent manipulations will almost surely displace the incus from view and it cannot be easily found. All grappling after the incus, when it cannot be seen, is inadvisable, as the incus will rarely be caught after being lost from view, and irritation of the entire tympanic cavity will surely follow rough probing in the attic after the misplaced incus.

3. With a curved two edged tenotome, now sever the tendon of the tensor tympani muscle, by cutting upward behind the short process of the malleus.

4. With a probe-pointed knife sweep about the entire periphery, seize the malleus at or above the short process, never below it, and withdraw the malleus and the membrana tympani attached to it.

5. The hæmorrhage is so slight in otitis media catarrhalis chronica, that gentle mopping with baked cotton is sufficient. I refrain from mopping with any fluid in these cases. The meatus should now be lightly stopped with baked cotton or iodoform cotton, and let alone for twenty-four hours.

My operations in all cases, both in chronic catarrh of the middle ear, and in chronic purulent otitis media, have been performed only after all other rational means have been tried and failed to give relief.

In otitis media catarrhalis chronica the operation has been undertaken to relieve deafness, tinnitus and vertigo, as all of these symptoms are often present in the same subject. Sometimes deafness occurs alone; but tinnitus is never found

in chronic catarrh of the middle ear without some deafness, and vertigo is never present in this disease without tinnitus and deafness. When deafness is present alone, even when the operation does not remove it, I have never known it to make the hearing worse, nor to be followed by tinnitus or vertigo. Regeneration of the membrane often follows, preceded by painless suppuration, or more commonly by an excessive discharge of clear, glairy mucus. Some numbness of the tongue, from section of the chorda tympani, may be felt in two or three days and continue for a short time after the operation, but it soon wears off.

In many cases of chronic catarrh of the middle ear, nothing else but this operation will benefit. So-called mobilization of the stapes, stretching the chain of bonelets, and section of the folds of the membrana, amount to nothing. The first two are probably never really done, as the stapes cannot be reached under inspection, in most cases.

Traction on the malleus simply, will not affect the stapes, and the lightest traction on the incus will detach it from the stapes. Traction on the stapes, if the latter can be seen and seized, will quickly break the crura. Section of the folds of the membrane, like simple incision in the sclerotic membrane, may improve the hearing for a few minutes or even hours, until the incision heals. No permanently good results can be shown to have followed these expedients, like those resulting from excision of the membrana tympani and the two larger ossicles.

Relief from a sensation of pressure in the ear is one of the most constant results of the operation. In some instances, signal relief from aggravated tinnitus and aural vertigo follows immediately upon the operation, and is permanent.¹ The least frequent result in otitis media catarrhalis chronica, is permanent improvement in hearing. Section of the chorda tympani nerve is of no consequence, as the numbness of the tongue produced by it disappears in a few days.

Organization of the Operation, in Chronic Catarrh of the Middle Ear.—The patient must be in fair health, and should live moderately for some days preceding the operation. The operation should not be performed during menstruation. After the operation the ear should be lightly stopped with baked cotton or 5 per cent. iodoform cotton; but not with bichloride cotton, as it may irritate the skin of the canal when kept in constant contact. Patients should remain in bed twenty-four hours after the operation, and in the house not more than five days. Then it is best to go out, at first with ear stopped with cotton, in all seasons of the year. It is advisable to avoid sudden motions of the head and anything tending to sudden congestion of the head.

¹ See case reported by C. H. Burnett, American Jour. Med. Sciences, February, 1890.

If suppuration or a mucous discharge sets in, cotton must not be worn in the ear, as it gets moist and macerates, and irritates the meatus. Regeneration of the membrana tympani interferes with none of the gains of the operation, excepting improved hearing; this is diminished, as a rule, by regeneration of the membrana, but not always, according to Lucae and others.

Conclusions, in Chronic Catarrhal Otitis Media.

—1. The operation of excision is attended with no bad results, even if it do no good.

2. The most constant result of the operation is a relief from a sensation of pressure and fullness in the ear.

3. The next most frequent result of the operation is the prompt, entire and permanent relief of tinnitus and aural vertigo (Ménière's symptoms).

4. The least frequent result is improvement in hearing. Sometimes, however, this is marked. If the hearing is improved by the operation, but diminishes upon regeneration of the membrana tympani, the latter can be broken down as often as it re-forms, until its reparative power is overcome. In some cases it appears that the improved hearing persists, notwithstanding regeneration of the membrana tympani.

5. In those cases of chronic catarrh of the middle ear, in which everything else has been tried without benefit, it would seem that the patient should have the chances of improvement offered by this harmless operation.

The Operation in Otitis Media Purulenta Chronica.—In some cases of chronic suppuration of the middle ear the operation has a wider field of application, and the results are better. Suppuration, after defying all other means, is checked by it. Thus the sequelæ of chronic purulent otitis media are warded off. It is especially useful in attic suppuration, with the sole perforation in the membrana flaccida. In such cases there is always necrosis of one or more ossicle, and sometimes of the surrounding osseous wall. By the operation necrotic ossicula can be removed, drainage of the attic secured, and direct medication rendered practicable. If the surrounding osseous wall of the attic is necrotic, it can now be reached conveniently after excision of the membrana flaccida and the two larger ossicula.

In suppuration of the atrium with the sole perforation in the membrana tensa (below the folds), it will be found, if the perforation is small and situated below or in front of the manubrium, that the disease is limited to the anterior portion of the atrium, that granulations and granulation tissue are flourishing on the inner surface of the membrana and in the front part of the tympanic cavity. In such cases, when the disease has been running on defiantly for years, it will yield quickly after the diseased tympanic wall and the granulations are treated—best, according to my ex-

perience, with chromic acid, which could not have been applied before the excision of the membrana.

The deafness is often astonishingly improved by the operation, rising from *nil* in some cases to 15 feet for isolated words of ordinary tones.² Tinnitus too is quelled, and vertigo and headache banished. The general health is markedly improved, after the removal of necrotic tissue from the ear. In many of these cases the patients have been suffering from a mild form of chronic septicæmia. In children the repeated gatherings in the ear are entirely overcome by the operation.

Since, in otitis media purulenta chronica, we have to deal with necrotic remnants of the conductors of sound, the operation varies greatly from that in otitis media catarrhalis chronica. It varies, in fact, in every case of otitis media purulenta chronica, according to the ravages of the chronic disease. Hæmorrhage is always more abundant and confusing in chronic purulent otitis media than in operations of chronic catarrh of the middle ear.

In otitis media purulenta chronica the first endeavor should be to expose the incus-stapes joint, if not already exposed, by a pathological perforation in the membrana tympani. If the incus is not diseased in any way, and still in connection with the stapes, it may remain, but if diseased in any point, either by granulations or caries, it must be removed. A view of this bone is more easily obtained in attic disease with a large perforation in the membrana flaccida, or when this perforation is enlarged by the knife. If the operation is applied in a case of attic suppuration, with the sole perforation in the membrana flaccida, the perforation should be enlarged so that the attic can be inspected, and examined with a probe for diseased bone. Caries of the malleus will invariably be found, and generally, too, the incus is carious or destroyed by necrosis. All carious tissues should of course be removed. In attic cases, the malleus may first be removed, as the incus cannot escape from view if present in the attic, with the large perforation in the membrana flaccida. If present, the incus should next be removed, and the surrounding walls examined for caries. If caries be found on the inner tympanic wall, very little, if any, scraping should be done there, because, now that thorough medication can be applied directly to the attic, carious bone tissue will tend to crumble off and the bare surface to cover in with muco-periosteal membrane, if the caries is not extensive enough to have caused the formation of a distinct sequestrum.

If the latter has formed, it should be promptly removed. Often it will discharge itself after the attic has been opened and drainage improved.

² See case reported by me, Philadelphia Med. News, August 16, 1890.

In purely attic cases the lower tympanum will often be found entirely free from disease. In very chronic attic disease, after destruction of the incus and the head and neck of the malleus, the manubrium and membrana tensa remaining intact, the atrium is converted into a pocket, which will be found filled with pus and cholesteatomatous masses, beneath which granulations will be found on the promontory and upon the inner surface of the membrana tympani, as in a case recently operated on by me, but not yet published.

If the case is one of chronic suppuration of the middle ear with the perforation in the membrana tensa, *i. e.*, anywhere below the folds of the membrana, the membrana flaccida being intact, excision should be performed in the same way as in a case of chronic catarrh of the middle ear, unless the perforation in the membrana is so large as to permit thorough inspection of the atrium and its examination with a probe. If the perforation is small and the discharge very chronic, granulations will be found on the inner surface of the membrana tympani and upon the inner wall of the tympanum.

The latter region is often of a uniform, velvety surface of granulation tissue, passing into true discrete granulations near the tympanic mouth of the Eustachian tube. The lower end of the manubrium may be found carious, if included in the periphery of the perforation.

* Such conditions in the tympanic cavity, revealed only by excision of the membrana, when the perforation in it is small, demonstrate the uselessness of the routine treatment usually pursued in such cases. These are the cases which, beginning with a muco-purulent discharge from the ear, in a child, proceed defiantly and uninterruptedly, no matter what the treatment, for years, until with impaired and decreasing hearing the membrana tympani is gradually sloughed away, the ossicles more or less destroyed by necrosis, and the drum cavity, both in the attic and atrium, choked with granulations and cholesteatomatous debris. Then the aditus and the atrium mastoideum, and the mastoid cells are invaded. Before the latter event, however, cerebral abscess may be developed, or sinus thrombosis and pyæmia may bring about a fatal termination. The least that happens in such cases is an impairment of hearing, and a chronic offensive discharge from the ear or ears.

Given, therefore, a case of chronic otitis media purulenta, with a small perforation of the membrana tympani and impaired hearing, which has continued for a year or more, and undergone all forms of ordinarily employed routine treatment, we all know the logical sequence of its natural history to be what I have just described.

We also know that the imperative demand upon the aurist is to arrest such a process as quickly as possible, not so much to save hearing

as to save health, and probably the life of the patient. Old methods will not do it in numerous cases, notably among those with poor hygienic surroundings. Defiant cases are common even among the wealthy, who are surrounded with every means of health. In excision of the membrana tympani and necrotic ossicles is offered an efficient and prompt means of stopping the purulency and preventing the ravages which will surely follow a continuance of the suppuration! The hearing and health of the patient will surely be improved, and his life rendered safer, because of the removal of the risk of sinus thrombosis, pyæmia and cerebral abscess.

There would be very little, if any, mastoid disease, if purulent otitis media in children were promptly cured. In many instances there is no way to check it but to perform excision of the membrana, and thus get at the disease while still limited to the anterior portion of the drum cavity, and before it has even made a large perforation in the drum-head. At once drainage is improved, and direct medication of the diseased mucous membrane can be carried out. Then solutions, powders and caustics can be applied rationally and with good effect.

The hearing will improve, the suppuration will be checked before reaching the attic or the mastoid, and a new membrana tympani will form, or the mucous membrane of the drum cavity assume a dry, white and shining appearance.

Conclusions in Cases of Otitis Media Purulenta Chronica.—1. The operation has not failed to stop suppuration in all the cases of chronic purulent otitis media in which the writer has applied it.

2. In attic cases with normal atrium, the sole perforation being in the membrana flaccida, this operation is the only means of cure.

3. By this operation, in cases of chronic purulent otitis media, in which the sole perforation is in the membrana tensa and is comparatively small, and while the purulency is limited to the anterior part of the drum cavity, the suppuration is promptly checked, before it has had an opportunity to attack the posterior portion of the drum cavity. Thus mastoid inflammation and necrosis, sinus thrombosis, pyæmia and cerebral abscess are prevented.

4. If any hearing exists before the operation, it invariably improves after the excision.

5. Vertigo, headache, tinnitus, and the ordinary attacks of ear-ache from "gatherings," so common in chronic otorrhœa in children, are entirely and permanently relieved by the excision of the necrotic remnants of the membrana tympani and the two larger ossicles.

A BRIEF ACCOUNT OF THE ETIOLOGY AND TREATMENT OF TINNITUS AURIUM.

Read in the Section of Laryngology and Otology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 6, 1891.

BY LAURENCE TURNBULL, M.D., PH.G.,
OF PHILADELPHIA, PA.

It is not the object of this brief paper to dwell at length on all forms of tinnitus aurium, but to omit those which are so well understood and treated by every well educated medical man; as, for instance, those caused by cerumen, pressing on the membrana tympani; inflammation or swelling; exostosis or abscess of the auditory canal; that large class caused by catarrhal changes in the tympanum or middle ear, and the Eustachian tubes; changes of structure with deposit in, or on, the membrana tympani with or without perforation and polypus in or near the same region. It will be our desire to dwell on the more obscure forms which we find in disease of the internal ear, labyrinth, auditory nerve, and above all, the reflex causes of deafness, with the most distressing forms of tinnitus.

It is now well known by you that there exists a connection between the auditory nuclei in the medulla, the pons, and the cortical auditory centers of either side of the brain, and that the "sense of hearing is in greater part situated in the temporal lobe, and more especially in the superior temporal gyrus of this lobe."

As Dr. Ferrier has stated in a letter, tinnitus may occur in both ears, as the result of unilateral irritation, the effect of the intimate connection of the auditory nerves and centres. The cases of sensory cortical discharges reported by Hughes Bennett may be advanced, Dr. Ferrier thinks, to establish this view. Ferrier writes that Baginsky states that the auditory nerve is in relation with the auditory centre of the cortex, through the lower fillet of the opposite side, and thence by means of the posterior tubercle of the corpora quadrigemina, and internal geniculate body to the medullary fibres of the cortex.

We may thus classify, according to Professor Jones, the principal sources of reflex irritation or inhibition of the auditory nerve: *a*, Through communications at the nuclei of origin; more especially might this occur through the sensory fifth and tenth nerves. *b*, Through the communications with the facial in the internal auditory meatus, the reflection from this connection being transmitted along the petrosal nerves from the otic and Meckel's ganglions, and the parts supplied by them. *c*, Through communications between the nerves supplying the tympanic structures, and Meckel's ganglion and the otic and geniculate ganglions. According to Foster, the activity of the tensor tympani muscle is regulated by reflex action. *d*, Irritations may be re-

flected to the cerebellum or the auditory centre and referred to the ear or different parts of the head. Most important are the researches of Gaskell as to the presence and course of vaso-constrictor and vaso dilator fibres (which control the blood supply by constriction or dilatation of the small vessels) arising, the former from the upper part, and the latter throughout the whole length of the spinal cord, and which pass to the cervical ganglions of the sympathetic, and thence (in this instance) to the special arteries, furnishing the supply of blood to the ear, more especially the internal auditory, from the basilar. Also, of importance is the fact that certain nerves, such as the trigeminus and cervical sympathetic, appear to be supplied with special "pressor" fibres (McKendrick), which have the power of constricting the vessels; this may occur either from a direct or reflected irritation of these fibres, which irritation, as in the case of the cervical sympathetic nerve, must have an important effect on the circulation in the ear. Of the various other nerve communications and distributions in the ear, which bear on reflex irritation, we would remind you of the connection between the glossopharyngeal, fifth, and sympathetic nerves, as, for example, the supply of the tensor tympani and stapedius from the otic ganglion and the facial nerves respectively; the communications in the tympanic mucous membrane, between Jacobson's nerve, the sympathetic, and the geniculate ganglion of the facial nerve, and the other communications between the carotid plexus of the sympathetic, Jacobson's nerve, and the otic and Meckel's ganglions, thus bringing all these nerve communications into direct relation with the superior cervical ganglion. The supply of the anterior wall of the external auditory meatus and the tympanic membrane from the auriculo-temporal is an important point bearing on reflex irritation from affections of the external meatus, which cause tinnitus, when the middle ear is healthy. This sensory supply, be it remembered, is connected with the facial and pneumogastric nerves.

The abnormal physiological conditions which are likely to cause tinnitus.—With regard to the physiology of hearing, it does not appear that there are any proofs that separate centres exist for the perception of different kinds of sound. A sensation arising from any irritation in the auditory centre may be referred to the periphery, that is, to the origin of the nerve filaments in the labyrinth (McKendrick). The receptive auditory centre is possibly in part situated in the cerebellum. An irritation occurring either in the labyrinth, the auditory nerve, or receptive centre, will, Professor McKendrick considers (in a communication which he has kindly written to Dr. Jones on this subject), "produce a stimulus in the hearing centre which will cause a sensation or a

series of sensations which will always be referred to the labyrinth. Such irritations may be caused by anything that interferes with the normal equilibration of the fluid in the labyrinth, by any direct or reflected irritation of the nerves of the external meatus, the middle ear, or labyrinth." They may follow or attend the presence of abnormal constituents in the blood which circulates in the respective centres, as well as alterations in the blood supply due to increase or diminution of blood pressure. This latter condition occurring either at the periphery, in the cerebellum, or in the course of the auditory nerve would be in itself sufficient to start an irritation of the hearing centre.

It has to be remembered, as Professor Kendrick rightly insists, how exquisitely sensitive the auditory nerve apparatus is, a fact with which all are acquainted who have studied the physiology of the ear in its perceptive powers, and its faculty of differentiating, analyzing, and synthetically arranging sound waves.

Vertigo.—Certain disturbances in the equilibration of the labyrinthic fluid, or reflex irritations of any part of the nervous apparatus of the labyrinth, or irritation of the auditory nerve nuclei, may cause the symptom of vertigo to accompany that of tinnitus. Stimulation of the cerebellum or cortical auditory centres may have the same effect; such stimulations may be reflected; deafness is not necessarily an accompaniment of the vertigo under these conditions, nor is it absolutely necessary that there must be local aural changes discernible in those suffering from the symptoms portrayed by Ménière.

Tinnitus Aurium Produced by Aneurismal Dilatation of the Left Posterior Auricular Artery.—We have had several cases of this form of tinnitus. In these there was a peculiar whistling and puffing sound (aneurismal thrill), caused by aneurism of the temporal branch of the internal carotid artery. In one case reported, the artery was tied with success. According to Hyrtl, there is in man a capillary which passes to the promontory. Might not affections of the tympanum frequently induce alterations in this vessel? Patients are sometimes relieved of pulsatile sounds by compression of the external carotid. The application of the continuous electric current is beneficial, particularly in passive congestion from vascular atony; it excites contractility, and causes the blood stasis to disappear.

The various forms of pulsating tinnitus are the result of aneurism or some alteration in the blood-vessels, anæmia, or excessive action of the heart; we must try compression of the temporal or carotid, diminishing the frequency of the heart's action by aconite or digitalis, or if the patient is anæmic, administer the salts of manganese, or lactate or citrate of iron, or the combination of iron and common salt. (Flint, New York.)

Very good results have followed their use in anæmic deafness with tinnitus.

We must make careful diagnosis, by exclusion, to discover whether we have excitement of the brain causing subjective noises, or on the other hand exhaustion from over effort or some drain upon the nervous system. In the first instance, we resort to bromide of potassium or sodium, or if there is any suspicion of syphilitic complication, add bichloride of mercury and the iodide of potassium, with the active principle of jaborandi to produce greater activity of the salivary and sweat-glands.

If it be from exhaustion, we resort to a solution of phosphoric acid employed in the form of "lemonade," or to the phosphites or hypo-phosphites, in conjunction with strychnia or its salts, and the use of the galvanic current to assist in completing the cure.

A case relieved by operation. Pulsating noises, with vertigo. Miss Maria C., the sister of a distinguished western physician, was sent to us with a letter, in which he stated that his sister had a persistent discharge from the right ear, in which she was almost absolutely deaf. She was a teacher of music, and had to be much exposed, out of doors, during all kinds of weather. She was very intelligent and cultivated, and was a skilled musician, but was most distressed about the discharge, and the odor, which was obvious in spite of great care. She was also much annoyed by the peculiar pulsating noises in that ear, and the dizziness was also so severe at times that she was afraid of falling, and had to grasp at any object for support. She had been treated by various means, but without success. Having been very successful in treating a nephew, she placed herself under our care, being quite ready to carry out all directions faithfully. After cleansing the ear, we found the membrana tympani perforated, the opening being in the upper inferior quadrant, but entirely closed with polypoid granulations which extended from the perforation all the way forward, involving the upper wall of the bony meatus. After removing the posterior mass by several operations, by the wire snare, pressure was made by a probe, and it entered a cloaca-like opening in connection with diseased bone, and this at once caused her a severe attack of vertigo, which lasted, even when the instrument was removed, several seconds.

By the administration of large doses of quinine and hydrobromic acid, and now and then an anodyne on account of pain in the part, she was able to allow the gradual removal of all the diseased bone by scraping with a small sharp, spoonlike instrument. We then applied the actual cautery, and, lastly, a ball of fused nitrate of silver on an aluminum wire. After many months of treatment it filled up with healthy granulations, and closed. The discharge gradu-

ally diminished, and the perforations healed by the use of boracic acid and solution of boro-glyceride. Several relapses occurred. She has been residing in the country, giving music lessons and doing Sunday-school work, and being out in all weather, but has had no severe relapse. Another method is proposed, first, by Lucca, and still another is the removal of the membrana tympani, malleus and incus; a method which is still *sub-judice*.

Spastic Contraction of the Intrinsic Muscles of the Eustachian Tube. *Diagnosis.*—Spastic contraction of the tensor tympani causing the noise in separating the mucus in the Eustachian tubes.

Treatment.—Inhalations of chloroform, and belladonna by the middle ear, to allay spasms, and valerianate of quinine and oleo-resin of cubebæ to act upon the nervous system and mucous membrane and the Eustachian tube. With the primary galvanic current in front of the ear and in the Eustachian tube by our intratympanic catheter, and this, together with the local application of a sol. argenti nitratis to the tonsils, diminished the sounds. The continued use of the battery, with the local application to the throat and mouth of the Eustachian tubes of the fluid extract of hydrastis canadensis by means of our Eustachian forceps generally afford relief. These cases may be arranged under two classes—one in which the spasm is involuntary, and not controlled by the will of the patient, and the other voluntary.

The Influence of Aural Diseases upon Nervous and Mental Disorders.—The neurologists and psychologists do not estimate the importance of this subject, or give it due attention in their examinations. Dr. Catlett reports the case of a man about fifty years of age, an enterprising, moral, sober-minded person, a successful merchant, who had enjoyed uninterrupted good health previous to the accession of the persistent and "peace-destroying" tinnitus, which caused him to abandon his business and give up family and friends; but in all his wanderings over the world he was still pursued by his tormentors, and finally shot himself the night after he had consulted with the doctor, who was unable to report whether the hallucinations had any association with aural disease, as the doctor was unable to examine the condition of the ears. In cases of insanity, which if not caused by, is increased and maintained by aural disease, this should be treated.

Our rule should be that if there is any hereditary tendency to mental disease, and the hallucinations are persistent, resembling any of the forms of which we have given examples, care should be taken that the ears be examined, and if it be possible, the symptom of tinnitus removed.

Always endeavor to encourage the patient by suggesting that an improvement may occur by

varying the treatment, and also by being able to state that the brain or auditory nerve is seldom involved, and that as a rule it depends in the great majority of instances on some slight change in the muscles, ligaments, or blood vessels of the middle ear, which may cause increased pressure in the labyrinth. Hundreds of such cases are relieved by simply removing the offending cause.

In the peculiar class, complaining of "Chirping of Sparrows" and "Musical Sounds." (Reflex Tinnitus.)—We place them on a mixture of sherry wine and tincture of nux vomica, five drops in a tablespoonful after meals, feeling sure the sounds depended upon some reflex irritation of the spine reflected to the semi-circular canals. The success of the treatment confirmed the diagnosis. The use of this drug entirely relieved the annoying symptoms after one month's treatment.

There are also certain occupations that increase the intensity of the noises, as in those engaged as telegraph operators, locomotive engineers, boiler-makers, and machine or mill-workers.

Mental Influences.—There are certain mental influences which increase or diminish these sounds. As occasioned by a happy frame of mind, the pleasant dry weather, such will often diminish the intensity. Worry or ill temper, meeting strangers, or wet, damp, cold weather, or intense heat, or a close room, will often increase these sounds. Pleasant occupation or active work, or riding in a carriage or railroad, will diminish them. Tinnitus is usually not so intense during the day time, but becomes much louder when everything is quiet, or at night. This is especially the case if the individual suffers from dyspepsia or indigestion. The subjective noises are produced or increased by sickness of the stomach, or during pregnancy and the puerperal state, and before menstruation.

There are various forms of reflected "reflex-tinnitus." Painful noises are produced in the ear from diseased condition of the kidneys, more especially diabetes, also in Bright's disease, which latter causes effusion of blood and serum in the middle ear, with a peculiar form of tinnitus, which can be removed by proper constitutional treatment.

Tinnitus caused by disease of the labyrinth is usually of a low pitch, and there is a "rushing" and a "humming," caused by increased pressure in the labyrinth forcing the stapes inward. The following are the usual means or agents employed in the treatment of labyrinthine tinnitus.

Treatment.—Pilocarpin, nitroglycerin, hydrobromic acid, ergot, mercury, iodide of ammonium and potassium and strychnine; these with the cholagogue preparations and some other measures have been found by us to be the most effective remedies if employed in the early stages. (See the author's "Manual of Diseases of the

Ear, p. 497, 2nd ed.) We report one case as showing the effects of a combined treatment:

Case 1.—John H.—Nov. 24, 1890.—In his 49th year; had distressing tinnitus aurium for one year; has been a chewer of tobacco and a smoker for the last ten years; becomes now and then intoxicated; enlarged liver; heart sounds indistinct; slight opacity with sinking of membrana tympani; countenance dull and face congested; circulation sluggish; taking bromide of potassium and chloral.

R. Ung. potass. iodide comp. to apply over liver.

R. Tinct. digitalis with spiritus ammonia arom. āā gtt. xx thrice daily in water for heart as a stimulant, and

R. Cerateum pilocarpin muriat. around ears.

R. Cerateum hydrarg. ox. flav. et morphia, used in the meatus on cotton.

Nov. 25.—No improvement; confined to house; messenger stated that the family were afraid of his becoming insane; did not sleep; filled up the ear with a 10 per cent. warm solution cocaine hydrochl.; opened Eustachian tube under ether vapor; made application of comp. sol. of iodine in glycerine to posterior nasal space; applied strong sol. of menthol in front of ear; also directed six ounces of blood to be drawn by leeches or cups from front of ear and mastoid process; ordered Sprudel salts; to repeat the anodyne solution of potassii bromidum with chloral at 9 P.M. and 12 M.; his head feels hollow; no dizziness, but "hissing sound" most of the time, which may be from diseased blood vessels; pulse normal, tongue white, bowels irregular; not to use tea or coffee, and continue to use laxative.

Nov. 26.—Leeches have bled well; slept but little; employed the anodyne mixture freely; states that "if he cannot get better he will go mad;" his general appearance is better; used hypodermic of $\frac{1}{4}$ gr. sulphate morphia and $\frac{1}{30}$ gr. nitroglycerin back of ear and occipital region; when under the influence of anodyne perforated the membrana tympani at lower quadrant and scarified the auditory meatus.

Nov. 27.—Did not sleep during the day, but at night he was able to sleep under the influence of a half grain of codeia; pulse 88; respiration normal; no pain; blood still discharged from the ear; opened the Eustachian tubes under ether, and administered hypodermic of $\frac{1}{30}$ gr. nitroglycerin.

Nov. 28.—Patient about the same; did not sleep with the use of the codeia; introduced $\frac{1}{30}$ gr. nitroglycerin and to take through the day every three hours $\frac{1}{100}$ gr. with mixture of bromide of potassium and chloral and a dessert spoonful of "bromo-caffeine." He states that he is "so anxious to get well" he is willing to take anything; pulse more steady and regular; have now made up my mind that the trouble is "alcoholism," with hallucinations which induce insanity if not relieved.

Nov. 29.—Patient came in advance of his attendant and stated that he was a great deal better, had but very little pain and that the noises were very much less, had taken a tablespoonful of the mixture of the bromide and chloral with two teaspoonfuls of the "bromo-caffeine" and had slept naturally all night; had taken his Carlsbad salts, which had operated also; had his hepatic region well rubbed with codine ointment, taking the increased dose, thirty drops in water, of Squibb's hydrobromic acid; a hypodermic of $\frac{1}{30}$ gr. nitroglycerin and $\frac{1}{8}$ gr. muriate of pilocarpin aristol was used in meatus.

Nov. 30.—Had a fair day and was able to sleep all night; had a slight increase of tinnitus after the last dose of hydrobromic acid.

Dec. 1.—Hypodermic of nitroglycerin $\frac{1}{30}$ gr., cleansing the ear with soda solution; still improving, and able to sleep, but took his $\frac{1}{100}$ gr. nitroglycerin every three hours.

Dec. 4.—Returned after absence of two days, still doing well; noises not so great; slept well; not to return but on alternate days, and requires no attendant; introduced hypodermic of $\frac{1}{150}$ gr. of nitroglycerin and gave him 100 pills, one to be taken three times a day; continue the other therapeutic agents.

Dec. 6.—Patient continues to improve, and was able to sleep all night; noises much less; bowels moved naturally, and able to take care of himself.

Dec. 8.—Patient feeling very much better; slept well, and had a good day; continued treatment; perforation open; secretion discharge ceased; scabs and dried blood removed later from meatus.

Dec. 10.—Still improving; cleansed ear; opened Eustachian tube under ether; examined liver, found the enlargement gone and much relieved.

Dec. 13.—Improvement continues; finds the inflation by Valsalva's method increases noises; Eustachian tube open, and throat and nose almost clear.

Dec. 16.—States to-day that he is "first rate;" noises not distressing him; cleaned the opening in the membrana tympana and made application to the throat.

Dec. 20.—Feels very well; scarcely any noise to-day; ear feels well; perforation open; throat doing well.

Dec. 24.—Is doing well, able to sleep, eat, and feels well.

Dec. 27.—Sleeps without anodynes; noises still slight, but not like the harsh sounds which he stated "seemed to raise even the bed blankets." Swelling over liver gone so that he can sleep on that side.

Dec. 31.—Feels quite well to-day, and has been since last visit; opened Eustachian tube with catheter and ether and directed to continue treatment until Jan. 24th, when he was discharged, feeling well enough to do without the doctor.

NATIONAL ASSOCIATION OF MILITARY
SURGEONS OF THE NATIONAL
GUARD OF THE UNITED
STATES.

CONCERNING THE ORGANIZATION OF THE MEDICAL
DEPARTMENT OF THE NATIONAL GUARD.

*Read at the First Meeting of National Guard Surgeons, at Chicago,
Sept. 18, 1891.*

BY J. D. BRIANT, M.D.,

SURGEON-GENERAL OF THE NEW YORK STATE NATIONAL GUARD.

While the title of this paper is sufficiently expressive, as it seems to me, to make its importance obvious to all concerned, still, it is not the intention of the writer now to do more than to speak of the medical officers of the Guard and their immediate aids. The scope of a complete organization for the duties of active service, as in the case of the regular army, is too extended to be considered at large at this time, and in fact it may be best considered by a careful study of the methods employed in the regular army itself. I shall deem it sufficient at present to dwell upon the necessity of what may be called self evident requirements of the medical service, requirements, the advisability of which are so obvious as to hardly need more than the mention to carry conviction to all minds. Those of you who are at the head of a well organized medical department can appreciate its importance to the service, as well as the assiduity necessary for its establishment. Those who are anticipating such a desideratum can but welcome the opportunity here offered to profit alike by the facts to be presented and the friendly criticism they will necessarily inspire. I shall speak of the Guard as an entirety, giving to it the comprehensive significance of the expression National itself. This course is proper, since the prime object of the organization is similar in all States—the protection of individual and public rights from organized and otherwise ungovernable violence. And, too, in each State, the Guard is sustained by the patriotism and local pride of the citizens of communities, who as willingly perform military duty in the Guard as they pay taxes for its support. It follows from these indubitable facts that the people of these communities, and of States even, expect, as they have the right to, a wise preparation for an efficient protection from violence of private and public interests, whenever the occasion demands it. And it is equally logical to say that their approbation and support of the Guard will be directly proportionate to the actual and prospective benefits which they contemplate or receive by reason of its existence. It, therefore, follows that the medical, like every other department of the Guard, should be so organized as to give to the greatest number the greatest good at all times that is consistent with military

efficiency. The necessity for such provisions in the medical department of many States is pregnant with the sentiment that teaches that :

The woes of the defenders
Of a country's cause
Should be soothed by a wise adjustment
Of a country's laws.

This sentiment refers not alone to the sense of grateful patriotism that contemplates a liberal and substantial recognition on the part of a country of those who have served in her defense, but also it implies a practical adjustment of matters by wise measures in times of peace, for the prevention and alleviation of physical disaster in times of strife. In the amplification of this idea I cannot help but believe that the medical department of the National Guard should be so constituted that it may extend "prompt aid" to the citizen-soldier and citizen-taxpayer at all times in case of physical emergencies. The consummation of this plan can but meet the hearty approval of those it is intended to aid, and will thus cause, on their part at least, a proportionate increase in the moral and financial support of the Guard. It has been my great honor, as well as pleasure, to have been connected officially with the Guard of New York since June, 1873. About ten years of this time were devoted to regimental service, a service that enabled me to study the needs of the medical department at large, and especially to note the deficiencies of the one under my immediate charge. During the remainder and later portion of the service—about nine years—I have, as surgeon-general of the State, been able, with the concurrence of the commander-in-chief, and the advice and individual support of the officers of the medical staff, to advance the status of efficiency of the medical department to a considerably higher plane than it formerly occupied. At the time of my entrance to the Guard, no properly authorized medical scrutiny of the professional qualifications of an applicant for the position of medical officer in the Guard had been established, except that he shall have graduated from a medical college; and this requirement was assumed to have been complied with quite as often as it was demonstrated to have been by the exhibition of fitting credentials. And, too, at this time it was necessary that the commandant of the organization be convinced that the applicant was a "good fellow," and would "fill the bill," at least in all respects essential to good-fellowship. Good policy and good principle often parted company at this phase of requirement. At all events, the essential qualifications that constitute a proper medical officer, in the professional sense, could be made subservient to the social, financial and political considerations of the laity sense. As the result of this policy, while many good and true men were recruited, yet many—indeed, too

many, in fact—were accepted who valued the commission only for the selfish gain they hoped for, rather than the honorable and useful record it might have in store for them. It is plain to be seen that a policy of this kind furnished not only indifferent medical service of the legally authorized type, but also opened the way for even a great abuse—the acceptance of those who were possessed of no legal qualifications whatever to practice medicine or surgery. Please do not misunderstand me; for while this abuse was of rare occurrence indeed, still the system was such that it need not have been the exception, in so far as official medical scrutiny exercised any control. It is not strange if, at this time, commanding officers often looked on their medical subordinates in the light of physical ornaments and conveniences, or as animated luxuries, to whom they might refer matters of a medical tenor for decision, when they felt condescendingly inclined, or when good policy dictated that their own opinion should have the genuine or implied approval of a medical officer. I will not dwell longer on the unfortunate realities nor the grave possibilities of this former course of action than to add that it was not the result of indifference or dishonesty, but simply a phase in the developmental history of the Guard. Please remember that this period is twenty years to the rear of the one of to-day, and although a continuous improvement was made in this respect by the cleansing influence of a ferment of earnest and wise purposes, and the survival of the fittest, still it was not till the issuance of an order, of which the following extracts are the greater portions, that the matter was placed on an official and enduring basis:

GENERAL HEADQUARTERS, STATE OF NEW YORK. }
 ADJUTANT GENERAL'S OFFICE.
 ALBANY, August 28, 1888.

General Orders No. 17.

1. Upon the recommendation of the surgeon-general, persons appointed to medical offices will hereafter be examined, before being commissioned, by special boards selected by the surgeon-general, and hereby appointed:

Returns of appointments of medical officers will be referred by the commanding officers of brigades to the boards appointed for their respective commands, and all concerned will be governed by the rules prescribed in General Orders No. 14, series 1887, from this office, so far as the same are applicable.

2. Appointees to medical offices shall be further examined in the standard branches taught in legally incorporated medical schools; the diagnosis and treatment of injuries and diseases to which troops may be exposed; the means employed for the urgent relief, and for the transportation of sick and wounded, including stretcher drill (see provisional manual of instruction, U. S. A.); camp and personal hygiene; and as to their knowledge of official papers relating to their department.

By order of the commander-in-chief.

JOSIAH PORTER,
 Major-general and Adjutant general.

Now please note the results of the enforcement of this order: The worth of a medical commis-

sion in the National Guard is greatly enhanced, and medical men of high attainments now seek positions in the service, serve faithfully, and wait patiently for promotion; the commanding officers respect their value and ability, and, therefore, seek their advice and heed it. The efficient, faithful and conscientious medical officers are now leavening the entire loaf of the medical service, and have become examples for emulation, instead of subjects of pomp or objects of pity, as they were often in the past.

The educational influences of the State Camp, which was established in 1882, and the introduction of rifle practice throughout the Guard, made the presence of the surgeon, and the importance of his attainments, thoroughly appreciated. Prior to 1887, the hospital stewards were of the most nondescript character. I recall well the fact that the first hospital steward coming under my charge in the regiment with which I was connected in 1873 was a stable-keeper. He was both faithful and honest, and his assiduity and endurance were phenomenal. His attention to duty was exceeded only by his entire ignorance of the preparation of medicines and their physical properties. For some time prior to 1887, I had advised that only such as were legally qualified to dispense medicines by the laws of the State relating to pharmacists should be permitted to act as hospital stewards of military organizations. However, my advice in this respect was not heeded until the occurrence of an object lesson which was so emphatic and pointed as to permit of no delay in the issuance, August, 1888, of an order, of which the following is an extract:

"The hospital steward of the regiment in camp, or, if there be none, a suitable person selected by the surgeon-general, will act as post hospital steward under the orders of the post-surgeon and the instructions of the surgeon-general. Such person or hospital steward must have passed an examination before the State Board of Pharmacy, and be licensed as a druggist according to the laws of the State; and regimental and battalion hospital stewards not so examined and licensed will not be recognized by the State, or permitted to act as hospital stewards. Regimental and battalion commanders ordered to camp duty whose hospital stewards do not meet those requirements will at once report the fact to these headquarters."

It may not be amiss now, in view of the importance of this order, to narrate the event that inspired its immediate promulgation, especially since this course may serve as a warning, and again aid in the establishment of a reform, the necessity for which at one time came near causing a most distressing accident, if not a fearful calamity in connection with the State Camp of New York. A lady, the wife of an officer of the general staff, visited the State Camp one evening

to witness the dress parade, and while there was attacked with a severe neuralgic headache, for the relief of which she wished me to prescribe. This I did, going myself to the camp druggist for the remedy, instead of sending an orderly with the prescription, as is the custom. The prescription called for a half grain of codeia and ten grains of bromide of potassium to be taken at once.

While waiting for the compounding of the remedy by the acting hospital steward of the organization then in camp, I leisurely leant against the center pole of the drug-store tent and made a casual survey of the contiguous tents and company streets. A moment after, and almost unconsciously, my attention was directed to the manipulations of this officer compounding the order, and I noticed that he had measured a considerable quantity of a whitish powder, which had not the appearance of bromide of potassium, and was too large an amount, I thought, for the required codeia. I asked, "What is that?" "Codeia," he said. "How much?" I inquired. He replied "One half a grain, as you ordered." "It cannot be possible that one half a grain of codeia will make so much bulk," I exclaimed. "Please balance your scales." He did as directed, weighed the powder again and found that there were six and a quarter grains of codeia instead of one half a grain as ordered. You will better appreciate my feelings and excuse this detail of statement, I think, when I tell you that the lady was the wife of the Surgeon-General himself, and that she would have been some distance from camp, no doubt, before the full effects of the drug could have appeared. This lesson is made still more impressive by the fact that the acting hospital steward at that time was an educated physician of some years' experience. And, too, it teaches in no uncertain manner that one unfamiliar with the physical properties of drugs should not be permitted to assume the duties of hospital steward.

Thus the uneducated hospital stewards were disposed of, so far as the service of the State camp was concerned. About one year later the final fatal blow was dealt to the system by the issuance of the following:

"It appearing that there are hospital stewards who are not qualified, according to the laws of the State, to perform the duties required of them, commanding officers are directed to discharge such from the service at once. Hospital stewards should have passed an examination before the State or county boards of pharmacy, and have secured licenses as pharmacists."

There remains but one other feature of the medical service to which I shall call your attention now—the education of a certain number of the rank and file in the simple methods of rendering "prompt aid to the injured." At the present

time, in the Guard of the State of New York, the plan of procedure is indicated with sufficient clearness by the following order, which paved the way to its enforcement:

GENERAL HEADQUARTERS, STATE OF NEW YORK.)
ADJUTANT-GENERAL'S OFFICE.

ALBANY, December 22, 1887.

General Orders, No. 36.

1. Commanding officers of regiments and battalions, and of batteries and separate companies having a medical officer, will organize ambulance corps in their respective commands as follows:

For a regiment or battalion, the corps shall consist of the medical officers of the command, the hospital steward, and three enlisted men from each company of seventy-five men, and two enlisted men from each company of less than that number.

For a battery or separate company, the corps shall consist of the medical officer and four enlisted men.

The enlisted men shall be detailed by the commanding officers, upon the recommendation of their senior medical officers, and there may be included in the detail for a regiment or battalion two corporals, and for a battery or separate company one corporal, but no other non-commissioned officers.

When the exigencies of the occasion require, commanding officers will detail such enlisted men as have already been found proficient, and may also detail musicians for duty with the corps.

Men detailed for ambulance service shall be relieved from such duty on the application of the medical officer having charge of the corps to which they are attached.

2. The corps shall be under the immediate orders, control and instruction of the senior medical officer of the command to which it belongs, but no assignment or detail for duty with the corps shall relieve an officer or enlisted man from his regular duties, except when on duty with the corps in active service.

3. To prepare the members of the corps for their duties, the medical officer in charge will provide a course of instruction. This course shall commence in the first week in January of each year, and continue during the drill seasons of the year, and shall be open also to such other members of the command of which the corps is a part, as may be approved by its senior medical officer.

The dates, hours and places when and where the instruction will be given, shall be published in orders to the whole command by its commanding officer.

4. The course of instruction given by the medical officers of the command shall include, for the present:

Rudimentary instruction in anatomy and physiology.

Rudimentary instruction in the diagnosis of the common accidents and diseased conditions to which National Guardsmen are exposed, and the common means for the prevention of the same.

Instruction as to the common means employed for the urgent relief of the sick and the injured, including stretcher drill and matters pertaining to transportation of the sick and injured.

Instruction in individual and camp hygiene.

5. At the close of the course of instruction, the detailed men of the corps shall be examined as to their proficiency, by a board to be appointed for that purpose, as hereinafter provided.

The senior medical officer of each regiment, battalion, battery and separate company, shall keep a record of the name, proficiency and general standing of each member of the ambulance corps under his charge, from the time of the first attendance of the member to the termination of his course of instruction, and also the result of his examination.

6. Commanding officers of brigades will, with the approval of the Surgeon-General, appoint for their respective commands boards of examination, which shall consist of not less than three medical officers, whose

duty it shall be to examine and report to the brigade commander as to the proficiency of the detailed men who have attended the prescribed course of instruction. These men will be ordered before the examining board on the application of the commanding officers of the regiment, battalion, battery or separate company to which they belong.

7. Enlisted men of ambulance corps, when actually on duty as such, are authorized to wear, in addition to insignia of military grade, around the left arm above the elbow, an arm badge (brassard) "of white cloth, 16 inches long and 3 wide, with a cross of red cloth 2 inches high and 2 inches wide in the centre."

8. An enlisted man who has passed the prescribed examination satisfactorily, and has the approval of the commanding officer of the brigade to which he belongs, will be permitted to wear at all times a badge, of a pattern to be prescribed in further orders, distinctive of the ambulance corps of this State, as an indication of a special fitness to aid the sick and injured under urgent circumstances.

9. Details for instruction in the duties of an ambulance corps will be made annually, at such time as will permit the course of instruction of each succeeding class to begin promptly in the first week in January.

10. There shall be allowed and issued by the Chief of Ordnance, as Acting Quartermaster-General, State Arsenal, corner Thirty-fifth St. and Seventh Ave., New York City, upon requisition made direct to him by the respective commanding officers, stretchers of a pattern approved by the Surgeon-General, at the rate of two for each regiment and battalion, and one for each battery or separate company having a medical officer.

By order of the Commander in Chief.

JOSIAH PORTER,

Major-General and Adjutant-General.

You will observe that the expression "ambulance corps" is employed in this order, and you will quickest comprehend the contemplated scope of the proposition embodied in the order, I think, if its aims be distinctly isolated at once.

1. The annual education of a definite number of men, many of whom would be declared competent by a board of examiners to render prompt aid to the injured comrade in times of strife, and to the comrade or citizen in the event of physical misfortune in times of peace. These to constitute the ambulance corps of the season.

2. The keeping of a yearly record of the proficiency of each of these men, with the view of the selection of those who are most serviceable when a serious occasion demands. This corps to be the ambulance corps of the occasion.

Already numerous instances have been brought to the attention of the State military authorities of the aid and comfort rendered by these men to the afflicted citizen in case of physical misfortune. And on all occasions in the service of the guard they have given wise advice and commendable injunctions to their comrades, and have promptly and efficiently spanned the important interval between the immediate demands for their own efforts and the arrival of a medical officer. It is proper to add in this connection that there is often much opposition on the part of commandants to making the details required by the order, so much in fact that the organization of a permanent corps instead is being given

a serious consideration. It might appear unjust on my part were I not impelled to add that this opposition is not a general one by any means, but one that is limited more especially to the smallest of the company and regimental organizations. However, in all of those commands in which unity of purpose, *esprit de corps* and personal pride of organization are the predominating features, the opportunity to acquire the knowledge is hailed with delight and eagerly accepted. I will now venture the statement that the interest and appreciation exhibited by military commands in measures best intended to increase and extend their importance and usefulness, and the earnestness of their coöperation in them, is in direct proportion to their prosperity, and to the confidence and esteem in which they are held by both the military and civil authorities. The badge mentioned in section 8 of the order is made of coin silver, and bears the red cross and the legend, "Prompt Aid to the Injured" on the face. Thus far it has been permitted to become the property of the winner, and is worn by him on all occasions, civil and military, as evidence of his ability to give prompt aid to the injured of all classes. It is now my opinion that the badge should be the property of the organization, in order that it may not be retained by those who are out of active military service, and for this reason may depreciate its value by its unwarranted use, and by failing to keep pace with the requirements of the service. At all events, some evidence should be retained by the worthy members at all times which will justify the belief that they are competent to perform their duties in this service, and will offer to them the opportunity and right of receiving instruction when sought for, and bear evidence of continued assiduity and competence on their part.

[NEW ORDER.]

GENERAL HEADQUARTERS, STATE OF NEW YORK, }
ADJUTANT-GENERAL'S OFFICE, }

ALBANY, September 3, 1891.

General Orders No. 23.

1. General Orders No. 36, from these headquarters, dated Dec. 22, 1887, providing for the organization of ambulance corps, and for the instruction of men detailed for ambulance service, is hereby revoked, and the following substituted therefor:

2. Commanding officers of regiments and battalions, and of troops, batteries and separate companies having a medical officer, will organize ambulance corps in their respective commands, but the corps in existence at this date in accordance with general orders No. 36, of these headquarters, series 1887, will be continued under the provisions hereinafter prescribed.

For a regiment or battalion, the corps shall consist of the medical officers of the command, the hospital steward, and as company bearers three enlisted men from each company of seventy-five men, and two enlisted men from each company of less than that number.

For a troop, battery or separate company, the corps shall consist of the medical officer and as company bearers four enlisted men.

The details for company bearers will be made by the

commanding officer of the organization of which the corps is a part, upon the recommendation of his senior medical officer. The men selected must possess the ability and intelligence necessary for the requirements of this service. There may be included in the detail for a regiment or battalion not more than two corporals, and for a troop, battery or separate company not more than one corporal; but if a member of the corps should be promoted to a non-commissioned office he shall be allowed, if he so desire, to complete the course of instruction, and after he has passed the examination prescribed below, the senior medical officer may select him as one of the non-commissioned officers authorized.

Men detailed to an ambulance corps shall be relieved from such duty on the application of the medical officer having charge of the corps to which they are attached.

Whenever actual relief for sick or injured is required, the commanding officer will detail such enlisted men as have attended the course of instruction, and may also detail musicians for such service.

3. When on ambulance duty, or under instruction, the corps shall be under the immediate orders and control of the senior medical officer of the command to which it belongs, but no assignment or detail for duty with the corps shall relieve an officer or enlisted man from his regular duties, except when actually on duty with the corps in active service.

4. To prepare the members of the corps for their duties, the medical officer in charge will provide a course of instruction. This course shall commence in the first month of the drill season of each year and be held at least once in two weeks during such season. It shall be open also to such other members of the command of which the corps is a part as may be approved by its senior medical officer.

The dates, hours and places when and where the instruction will be given shall be published in orders to the whole command by its commanding officer.

5. The course of instruction, given by the medical officers of the command, shall include, for the present:

Rudimentary instruction in anatomy and physiology.

Rudimentary instruction in the diagnosis of the nature of accidents and disease manifestations to which national guardsmen are subject, and the common means for the prevention and treatment of the same.

Instruction as to the common means employed for the urgent relief of the sick and the injured, including stretcher-drill and matters pertaining to transportation of the sick and injured.

Instruction in individual and camp hygiene.

6. At the close of the course of instruction, the detailed men of the corps shall be examined as to their proficiency by a board to be appointed for that purpose as hereinafter provided.

The senior medical officer of each regiment, battalion, troop, battery and separate company shall keep a record of the name, proficiency and general standing of each member of the ambulance corps under his charge, from the time of the first attendance of the member to the termination of his course of instruction, also the result of his examinations, and the number of the badge if one is awarded to him.

7. Commanding officers of the brigades will, with the approval of the Surgeon-General, appoint for their respective commands boards of examination which shall consist of not less than three medical officers, whose duty it shall be to examine and report to the brigade commander as to the proficiency of the detailed men who have attended the prescribed course of instruction. The presiding officer of each board shall notify the commanding officers of the organizations of his brigade of the dates on which the board will be in session, and when they will examine the detailed men of the respective corps. These men shall then be ordered before the examining board by the commanding officer of the regiment, battalion, troop, battery or separate company to

which they belong, and those who pass the prescribed examination shall form the ambulance corps of their respective organizations, and remain members of the same subject to the approval of the medical officer in charge, and subject also to an annual examination by the board mentioned.

8. Enlisted men of ambulance corps, when actually on duty as such, are authorized to wear around the left arm above the elbow (non-commissioned officers as far above the chevron as practicable) an arm badge ("brassard") of white cloth, sixteen inches long and three wide, with a cross of red cloth two inches high and two inches wide in centre.

9. An enlisted man who has been detailed to an ambulance corps, and who has passed the prescribed examination satisfactorily, and has the approval of the commanding officer of the brigade to which he belongs, will be permitted to wear, with the consent of the commanding officer mentioned below, while a member of the corps, on dress and undress uniforms, and when in citizen's dress, the badge of the ambulance corps of this State, of the pattern heretofore issued, as an indication of special fitness to aid the sick and injured under urgent circumstances; this badge shall be turned into the regimental, battalion, troop, battery or company commander of the soldier, when the latter ceases to be a member of the organization, and such commander shall be responsible to the State for the same, and shall have the power for good reasons to refuse permission to wear or decline to issue the same to any one.

10. Details to fill vacancies in the ambulance corps will be made upon the recommendation of the medical officers, if possible from those who have attended the course of instruction, and who appear upon competitive examination to be best qualified for the duties.

11. When a member of the ambulance corps ceases to be a member of the regiment, battalion, troop, battery or separate company, he shall receive, from the Surgeon-General of the State, upon the recommendation of the medical officer and the commanding officer, as evidence of his special qualifications and ability to perform the duties of the corps, a certificate to that effect, which certificate will entitle the owner to receive instruction in the duties of the corps at regular intervals, and to be examined in the same, and to have the result of the examination indorsed on the certificate.

12. There shall be allowed and issued by the Chief of Ordnance, as Acting Quartermaster-General, in cases where such issue has not already been made, upon requisition made direct to him by commanding officers, stretchers of a pattern approved by the Surgeon-General, at the rate of two for each regiment and battalion, and one for each troop, battery or separate company having a medical officer.

13. The Brigade Commanders and the Surgeon-General, and under him the brigade surgeons are charged with the prompt execution of this order, in their own sphere, and the latter and the Surgeon-General, in matters of instruction and advice, will communicate directly with the medical officers in charge of corps.

By order of the Commander-in-Chief.

JOSIAH PORTER,
Adjutant-General.

Official.

—Ass't Adj't General.

I will not detain you longer, as, it seems to me, sufficient has been said already to provide a substantial foundation for wise action in the future. Permit me, in conclusion, to offer the following recommendations for your consideration:

1. The requirement that all medical applicants should be caused, before entering the Guard in

the capacity of medical officers of commands, to pass an examination that shall be a rigid test of their ability to meet the demands of the position which they seek.

2. The requirement that all hospital stewards shall be fully qualified by law or by practice to dispense medicines intelligently and correctly.

3. The requirement that a suitable number of intelligent members of a command be instructed, examined, and be passed when proficient in the details essential to the rendering of "prompt aid to the injured," and of bestowing wise care on the sick.

4. The requirement that such worthy members be permitted to have in their possession a suitable badge, or other testimonial, at all times, as evidence of their ability.

In conclusion, permit me to express the belief that the formation of a scientific body from the medical officers of the Guard should be made secondary to the development of an efficient system of practical medical service in the Guard. And even then it seems to me that it can but be based upon an uncertain and fickle tenure, so long as no wise and judicious control can be exercised as to the *personnel* of its membership. It ought not to be overlooked that the commission bestowed by the State is the certificate of membership, not the requirements that few or many of the members may see fit to demand. Not to recognize a commission issued to its representative by a State or Territory is subversive of discipline, and can but lead, in my judgment, to dense demoralization, unmannerly bickering, and the breeding of life-long animosities, all of which are destructive of harmony and efficiency, and contrary to the laws and traditions of the service to which we belong.

BOOK REVIEWS.

A TREATISE ON THE DISEASES OF INFANCY AND CHILDHOOD. By J. LEWIS SMITH, M.D., Clinical Professor of Diseases of Children, Bellevue Hospital Medical College; Physician to Charity Hospital; Physician to the New York Foundling Asylum; Physician to the New York Infant Asylum; Consulting Physician to the Department of Children's Diseases, Bureau of Relief for the Out-door Poor, Bellevue; Consulting Physician to the Nursery and Child's Hospital, County Branch; Consulting Physician to the Infants' Hospital, Randall's Island. Seventh Edition, thoroughly revised, with Fifty-one Illustrations. Philadelphia: Lea Brothers & Co. 1890. Chicago: A. C. McClurg Co., 117-121 Wabash Ave. Price, cloth, \$4.50; sheep, \$5.50.

Six editions of this work have been presented to the medical profession. The seventh being in demand, the opportunity was given for a thorough revision of the entire book, of which Professor Smith has so fully availed himself, that not only has the volume been increased to nearly double its former size, but in its revision he has been able to incorporate recent investigations and

discoveries pertaining to the bacterial origin of many of the diseases of infancy and childhood—without which it would not meet the present requirements of the profession.

Very properly, in the first hundred pages, the subjects of food, bathing, clothing, sleep and exercise are dealt with, and in a manner highly satisfactory. Diseases of the newborn and constitutional diseases are very fully described, and in addition to the author's views as to their pathology and treatment, citations are freely made from a large number of our most accredited authors bearing upon the affections successively considered. A special feature of the work is the prominence given to diseases of the cerebro-spinal system, while those of the digestive apparatus and of the circulatory system are amply delineated, and methods of treatment are very fully considered.

The careful consideration given to "new remedies" will be helpful to those not yet familiarized with their actions and the conditions in which their uses are indicated.

The present revision gives a greatly added value to the work, and, as in the past, it will continue to be one of our most reliable and helpful treatises on diseases of infancy and childhood.

PAINFUL MENSTRUATION. By FRANCIS HENRY CHAMPNEYS, M.D., M.A., Oxon., etc. Published by H. K. Lewis, London.

This little brochure of nearly 100 pages consists in substance of the Harveian lectures for 1890. The subject is not only an important one but in the author's hands has been developed into one of great interest. Unlike the majority of English authors Dr. Champneys has a succinct and practical style which is a *sine qua non* in medical monographs. The subject of membranous dysmenorrhœa received considerable attention, several large tables being appended which contain the complete bibliography of this interesting subject. The busy practitioner will find the work a valuable one.

PARKES MANUAL OF PRACTICAL HYGIENE (eighth edition) edited by J. LANE NOTTER, M.A., M.D. Published by P. Blakiston Son & Co., Philadelphia.

This is an old friend in a new garb. The work has been thoroughly revised and brought up to date. The standard character of the work is so universally acknowledged that it is hardly necessary to state that it is among the best works upon practical hygiene that have ever been published.

TRANSACTIONS OF THE 12TH ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION. Published by D. APPLETON & Co., N. Y.

This little work is a digest of the proceedings of the 12th annual assembly of the American Laryngological Association held in Baltimore, Md., May 29-31, 1890, inclusive, and is certainly suggestive of the enterprise and character of the members of this society—and is well worthy emulation by other medical organizations. Its pages are replete with many well written articles on laryngological and rhinological topics, together with discussions thereon. Its initial article is in substance a very practical address by Dr. Jno. N. McKenzie, president of the society, who gives in outline the objects of the association and shows the practical and great good that has followed the organization. Altogether it may be said that the work can be perused with advantage by both the general practitioner and specialist.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, SEPTEMBER 26, 1891.

SOME RECENT RESEARCHES REGARDING GASTRIC DISEASES.

The announcement of a New York publishing house that a translation of EWALD'S last work on gastric diseases is in preparation, is an indication of the growing importance of the teachings the modern German school. We know of only a few instances where the diagnostic methods of EWALD and his followers have been employed in private practice, although in some of our hospitals they have already become an established procedure. Briefly stated, they consist in a withdrawal of some of the contents of the stomach at certain timed intervals, the analysis of these abstracted specimens by specially chosen tests, and in the administration of what are designated as "test meals" which are subsequently to be chemically examined. No small part of the labor involved in the building up of this new system of diagnosis and treatment has been in the selection of trustworthy reagents that may be not too elaborate for ordinary clinical employment. In order to be successful the tests must not only be fairly accurate and demonstrative but they must be capable of easy application. In this manner, a more intimate acquaintance with the gastric juice, especially in its relations to the outflow of its hydrochloric acid component, is obtained. For example, this acid is not secreted

at once after the entry of food into the stomach, for during a period of half an hour to fifty minutes after food lactic acid is the only acid present, probably yielded by the carbohydrates and meat ingested. Hydrochloric acid then appears and the two acids coexist for a time, but hydrochloric acid should be the only one present from ninety minutes to two hours after ingestion. It is in that period that gastric digestion proceeds most actively, and after that function is performed the acid is not present in the stomach. The flow of hydrochloric acid may be retarded or hastened by the character of the meat taken; the carbohydrates, for instance, when in excess tend to repress its secretion, or a meal of cooked albumen only may cause it to appear as early as fifteen minutes after ingestion. With a mixed diet this acid will appear within fifty minutes, and will remain for two hours or longer in proportion to the size of the meal and the amount of gastric function called into exercise. The stomach should be empty three to four hours later, or five to six in all, although the health-limits vary greatly. Longer than six hours is nearly always beyond the period of changes other than those that are fermentative in part, at least; and after seven hours those changes only are observed. The "test-meal" may be either a breakfast, as preferred by JURGENSON, or a dinner as practiced by VON SOHLERN, and the time for collecting the gastric contents may extend from two hours to three and half hours after the meal. Milk is seldom used, as it has the property of mystifying results by itself combining with hydrochloric acid. The meal may consist of a little weak tea with bread and butter, and at times an egg. When the desired time has arrived for withdrawing the gastric specimen, a soft rubber nasal tube is passed either through nose or mouth into the stomach. The patient should be in the recumbent posture with head turned downwards; pressure with the hand is then made over the patient's stomach and he is directed to cough. Following this procedure—to be repeated if necessary—there flows through the tube some of the gastric fluid, which is collected in a flask for examination. VON JAKSCH recommends the use of the unfiltered fluid, but filtration is more commonly employed. The acidity of the filtrate—when the latter course is chosen—is determined by the reaction obtained by the addition of phenol-

phthalein and sodium hydrate in certain known proportions which enable the results to be read off in terms of hydrochloric acid.

The test for lactic acid is generally by means of UFFELMAN'S reagent of liquor ferri perchloridi with carbolic acid. The reactions obtained from these tests, from GÜNZBERG'S phloroglucian-vanillin test and from D. J. HAMILTON'S modification of LEO'S test for free acid are summarized in an article by DR. JOHN MICHELL CLARKE of Bristol, in the *Medico-Chirurgical Journal* of that place. The use of EWALD'S salol test has lost some of its currency within the past year, but it is still regarded as one of the useful means for approximating the digestive period. Salol is not changed in the stomach, but it is broken up in the duodenum into phenol and salicylic acid, and this latter passes without delay into the urine, giving the characteristic deep purple coloration on the addition of perchloride of iron. The argument of EWALD was that the time of its detection in the urine gauged the motor power of the stomach, but this time is subject to some variation. So that HABER states the test in another way; that is, he would formulate the gastric mobility from the time of the disappearance of the salol reaction from the urine. Normally the salicylic acid is no longer discoverable twenty-six hours after the meal, whereas in cases of impaired power it continues to respond to the iron test from thirty to thirty-six hours. The practical application of the knowledge obtained from these constantly improving lists of tests is of wide bearing both to dyspeptic functional difficulties and to organic lesions, such as dilatation of the stomach, gastric ulcer and carcinoma. As between gastric ulcer and cancer the test for hydrochloric acid is considered to have important differential weight, for according to our present light, that acid is generally absent in the latter affection; while in the former it is always present and is, as a rule, of increasing or increased secretion. KOLLMAR has recently pointed out in the *Berliner Klinische Wochenschrift*, that a negative reaction lacks several points of being pathognomonic of gastric cancer, since that reaction may be yielded in cases of persistent fever, of œsophageal and duodenal cancer, of amyloid degeneration of the gastric mucosa, of poisoning by acids, and not infrequently in catarrh from atrophy. A temporary ab-

sence of hydrochloric acid may occur in dilatation of the organ, but the acid tends to reappear after a repeated washing out of the stomach. So that, if the exceptions be borne in mind, the absence of hydrochloric acid is a strong diagnostic aid in cases where the existence of cancer is uncertain, but seems probable from the concomitant condition. In eight cases of cancer, observed by DR. CLARKE, in which he examined the gastric contents several times, in each case the acid was absent every time the examination was made. In one case, of especial interest, from the fact that the gastric walls were not the subject of extensive infiltration, the acid was not present, but the writer is not yet able to declare that the early stages of gastric carcinoma are marked by the negative test.

It is not contended for these methods of diagnosis that every case of dyspepsia should be submitted to its somewhat complicated ritual, but it will be a relief to not a few of our practitioners to observe the simplifying of the tests employed in the prospect of the utilization of some of them in difficult and rebellious patients and those resistant to ordinarily successful plans of treatment. These new methods become peculiarly acceptable where neoplasm or ulcer becomes suspected, or as KOLLMAR has shown can take place, where the type of the lesion changes. Cancer may, although infrequently, develop in the cicatrix of a healed ulcer, a succession noted by that writer not less than fourteen times. As a practical point, DR. CLARKE offers in the conclusion of his paper the suggestion that the soft india-rubber tube only be used, in entering the stomach, without the stiffened end, such as is sold under the name of the JAGUES patent, which answers the purpose perfectly well and avoids the risk of doing an injury even in cases of ulcer.

ALIIS INSERVIENDO CONSUMOR: OR FOUR DECADES IN PRACTICE.

To one who, having borne the burden of the day, can sit down and write in jubilant strain of his professional life, his fellows and his juniors are constrained to listen. Such an one is DR. WILLIAM W. PARKER, of Richmond, Va., and President of his State Medical Society, and he is the author of a most readable little address before the alumni of his medical college, delivered in

April last. His subject was "Forty Years a Doctor," and it wavers like a pendulum between the joys and sorrows of his professional life, but joyous at the end in the consciousness of a race well run, and of much good done to others. Two score years of service finds him saying to his juniors: "Do not think that the bad treatment you have received is a lot exceptionally hard. All your predecessors, without one exception, have had the same hard fate. Nevertheless, I advise you to love all your patients from the start; it will make your work easier and more pleasant. Besides, it is your duty to trust, though you may be deceived." DR. PARKER evidently has that philosophy and kindly temperament which led a distinguished physician and magistrate of Amsterdam to adopt for his symbol the burning lamp, with the motto *Aliis inserviando consumor*. This was NICHOLAS TULPIUS, the central figure in REMBRANDT'S picture of the anatomical lesson. Gratitude may come to the physician for his self-consuming labors—"for there are those who gave us their confidence in early life and maintained it to the end, who are indeed jewels"—but that sentiment is not to be counted upon. Concerning the too frequent tendency to change from one physician to another, DR. PARKER says, "Many lives are lost yearly by a change of doctors." Another expression of his is, "The cooler you are, the wiser and safer you are; a highly nervous man is not fit for a doctor, nor a lazy man, nor yet a heartless man. Not to be bold and quick in emergencies is sometimes death to your patient." To the recent graduate he gives this advice: "So soon as you get your diplomas, get also a copy of the Code of Ethics of the American Medical Association, and carefully study it. It will teach you how to behave towards your medical brethren. I find that there is more need of the Code now than there was forty years ago. We are governed by the highest ethical code of any profession known to the world."

Many another striking remark occurs—too numerous for further quotation here—agreeable to all sensible minds, provided that they have not taken a prejudice in the opposite direction. Some of DR. PARKER'S observations are not wanting in eloquence, especially his little story about the largest fee he ever got, namely, the heartfelt thanks of a little orphan Irish girl of eight years of age: it is a hint for a great medical picture.

She simply said, "Thank God, here comes the doctor!" a cry which, the Doctor thought, went as straight to Heaven as that of any priest or seer, and he felt that even his name had been pronounced aloud and honored in the courts of Heaven.

Since the above was written another small pamphlet of DR. PARKER has fallen under our notice. It is from the transactions of the Virginia Medical Society, 1890, and treats of the rise and decline of homœopathy. One short paragraph we desire to select from it, for the purpose of illustrating the happy way our author has of touching up the subjects of his choice. He says: "It is very strange that HAHNEMANN did not see the defect in his new system, *since it excluded surgery, the most brilliant and useful branch of the medical art*. It is inseparable from the practice of medicine. No man can be a good surgeon who does not understand the action and use of drugs."

In conclusion, we may remind our readers of still a third paper by Dr. PARKER, published in these columns on June 6, an ingenious essay on the instinct of animals, taking side against the Darwinian argument about the "missing links" between human and animal intelligence. The bent of mind and flow of language seem to make literary work congenial to DR. PARKER, and if we are correct, we would encourage him to keep his pen ready to dip into the inkstand, as he from time to time conjures up the interesting scenes of the forty years of a doctor's life.

"AUGUST TWENTY-NINTH, THE POET'S DAY."

This is DR. HOLMES' day. His eighty-second natal day was quietly and comfortably celebrated at his home, and kindly remembered in hundreds of journals throughout the land. Some of the remarks of the editors were over-kind and tended to become hyperbolic. What shall we say of such an effort as the one which represented that if HOLMES' time of departure from earth were to come, "Death will knock off work and cling to HOLMES' coat-tails, even though he knows that he will be stopped at the gate," but he will hang around on the outside, in the bare hope that HOLMES will not be satisfied with the heavenly choir, and will possibly like to return to earth again? HOLMES himself speaks more sensibly

and more to the purpose when he says: "My health is excellent. I am very well and very happy. My eyesight troubles me somewhat, so that I am very glad to avail myself of the services of a secretary, and I am a little troubled at times to recognize my friends and acquaintances on the street. Perhaps some of them may have thought that I have intended to cut them; but it is only a little trouble with my eyes which causes me to pass them. Other than this I have no physical trouble."

THE NATIONAL ASSOCIATION OF MILITARY
SURGEONS OF THE NATIONAL GUARD OF
THE UNITED STATES.

We have the pleasure of welcoming another National organization of medical men. The medical officers of the militia of the several States have during the past few years grown into the habit of forming State societies among themselves. But it occurred to PROF. NICHOLAS SENN, Surgeon-General of Wisconsin, that the time had come to unite the medical officers of the militia into a National Organization. Accordingly, on his call, representatives from sixteen States met in Chicago September 18, for organization. In the morning the gentlemen attended a brilliant clinic, held by PROF. SENN, at the Presbyterian Hospital, a gunshot wound very properly forming the subject-matter of the clinic. At noon, to the number of sixty, at the Union Club, they sat down to a delightful lunch, tendered them by the Faculty of the Chicago Polyclinic, after which they marched, as befitted their military character, to the Chicago Polyclinic, whose handsome amphitheatre, appropriately decorated, became the theatre of their deliberations. In the evening, PROF. SENN'S residence was the scene of a brilliant reception given in honor of the military guests.

All organizations of medical men are beneficial to the profession, if for no other reason than that they bring physicians together, and thereby broaden them and cultivate better feelings among them. In addition, each special organization has its special uses. The advantages arising from the present organization are peculiarly its own, and it will secure improvements which can be obtained through no other channels. The *personnel* of the militia surgeons has, in the past, been too closely connected with politics to be above re-

proach. Such a state of affairs will be largely corrected through this organization, for it will attract to itself only the competent men of the service. It will foster the study of military surgery, altogether too much neglected. It will emphasize the importance of the medical art to the State.

We were pleased to note the presence of medical officers from the regular army at the organization of this Society. Several very interesting and valuable papers were read before the Society, one of which, that of GEN. BRIANT, of New York, appears in our issue of this week.

The Association elected the following officers: GEN. SENN, President; MAJ. NELSON H. HENRY, of New York, First Vice-President; COL. E. CHANCELLOR, of Missouri, Second Vice-President; COL. MATTHEWS, of Illinois, Secretary; LIEUT. RALPH CHANDLER, Corresponding Secretary; and COL. T. T. CRANE, of Colorado, Treasurer.

St. Louis was selected as the next place of meeting.

PRELIMINARY MEDICAL INSTRUCTION.

A plan for guiding the work of the medical student during the year under a preceptor, before entering college, has been adopted by the College of Physicians and Surgeons of Chicago, which appears worthy of a wider employment. The students are matriculated in the same manner as are the resident students, and are required to make weekly reports of progress and pass satisfactory examinations. The subject-matter of the course, as will be seen from the following, is particularly commendable:

COURSE OF STUDY.—The study of biology and physics is looked upon by the faculty as the most desirable foundation for the study of medicine and surgery. It has not been thought advisable to duplicate the resident course, but rather to supplement it. The following outline will give an idea of the plan of study as prepared by the faculty:

1. BIOLOGY.—*a.* Invertebrate Anatomy and Physiology.

The lessons during the first month comprise the study of the fresh or salt water clam and the craw-fish or lobster. Dissections, drawings, and four written examinations.

b. Vertebrate Anatomy and Physiology.

The next three months will be occupied in the study of the frog, the hen and the rat or the rabbit, and other accessible vertebrates. Dissections, preparations, drawings and twelve written examinations.

c. Anatomy of Plants and Methods of Histological Study.

The remainder of the year will be occupied in the study of the physiology of unicellular plants, germination, methods of histological study, and such other subjects as will be suggested in the progress of the initial course.

2. PHYSICS.—a. The reading of a suitable text-book on physics, weekly examinations during the whole course.

b. Experimental work which can be carried out at home with the material accessible in any village and with little expense.

3. LATIN.—It is recommended and expected that every student undertake at the same time the study of Latin under a competent teacher.

THE INFECTIOUS DISEASES INSTITUTE AT BERLIN.

The new institute, which is designed to be under the direction of DR. KOCH, at Berlin, was only opened August 17, and the first six patients were brought in that same evening. PROFESSOR BRIEGER has been appointed over the clinical department, and DR. PFEIFFER over the scientific laboratory. DR. BEHRING is among the assistants. The nursing has been assigned to the Brandenburg Sisterhood, a body ignoring all sectarian distinctions.

SOCIETY PROCEEDINGS.

Philadelphia County Medical Society.

Stated Meeting September 9, 1891.

THE PRESIDENT, JOHN B. ROBERTS, M.D., IN THE CHAIR.

DR. EDWARD JACKSON read a paper on

AN OPHTHALMOSCOPE FOR GENERAL USE.

It would be a great gain to both doctors and patients if a much larger proportion of those who class themselves as general practitioners were able, when the need for it arose, to use the ophthalmoscope. One who has no practical experience with it cannot even properly appreciate what he reads or hears of ophthalmoscopic appearances. And there are in the aggregate many cases in which the progress of general disease could be far more intelligently followed by its routine use, without entering upon debatable ground or attempting to use symptoms of doubtful significance.

With the ophthalmoscope, as with other instruments, the cheap instrument is very apt to lack certain important features, and the costly

instrument is mainly confined to the possession of those who mean to use it a good deal. It took many years to adapt the microscope to the needs of clinical work, to rid it of mechanical stages and other mechanical nuisances, and perfect its really essential parts. And the ophthalmoscope must pass through a similar pruning and adaptation before its use can be truly popular and common in the profession. For some years I have been working at this problem, and herewith present my results.

The ophthalmoscope for general use must, First, be one in which the difficulties of using the instrument are as far as possible overcome. Second, it must be one that will be as satisfactory as any of the best instruments for any case that is likely to be encountered. Third, it must be cheap. For this one I have no hesitation in claiming that with it the fundus of the eye can be seen as readily as with any ophthalmoscope heretofore made; for all practical purposes as a refraction ophthalmoscope, its lens series is complete; it can be bought for eight dollars.

It is easy to see through, because the mirror, which is circular, 30 mm. in diameter, tilts each way to the best angle, at about 25 or 30 degrees; it has a shorter canal, and wider lenses than have most first-class refraction ophthalmoscopes; each lens is retained in exact position by a spring stop; and all the lenses or combinations of lenses are available without taking the instrument from the eye.

The lens series is furnished by combinations of six lenses in two slides, and consists of convex 1, 2, 3, 4, 6, and 12 dioptres; concave 1, 2, 4, 6, 10, and 22 dioptres. To appreciate this series one must bear in mind the degrees of ametropia that are commonly encountered in practice. Among 4000 eyes, the statistics of which I have published in the *Transactions of the American Ophthalmological Society* for 1889, only one eye had hyperopia of 13 dioptres, and only one eye had myopia of 23 dioptres.

The series does not contain half-dioptres, which are given in all the larger refraction ophthalmoscopes: but a very prominent ophthalmologist has recently said that he had the half-dioptre lenses taken out of his large instrument (Noyes's modification of Loring's) as comparatively worthless. Under especially favorable conditions there are a few ophthalmoscopists who have constant and extensive practice with the instrument who can, I believe, measure refraction with a little more exactness with half-dioptre lenses than they could with only whole-dioptre intervals. But the ophthalmoscopists that can do this are comparatively few, the cases in which they can do it are few, and the practical value of doing it is utterly insignificant. For those who are not in special practice half-dioptre intervals are always a delusion and a snare, a hindrance,

a cause of inaccuracy. They are, therefore, discarded.

Although the statistics above referred to show that in but one eye in 40 of those encountered in practice is the degree of ametropia over 6 dioptries, to one not very familiar with the properties of lenses the intervals between the stronger lenses of this series may seem too great. Such must be reminded that the effect of every intermediate lens strength may be obtained by slightly varying the distance of the lens and instrument from the patient's eye. Thus the convex 6 dioptric lens acts as such only when placed against the eye, by drawing it back less than three inches it is made to act as a 12-dioptric lens, and within that space will correct any intermediate amount of hyperopia. By withdrawing the 12-dioptric convex lens a little over one inch it takes the place of a 20-dioptric lens. On the other hand, by withdrawing the concave 22-dioptric lens a little over two inches its effect is diminished to 10-dioptries, and in that space every intermediate strength is reproduced. In the same way the withdrawal of the 10 dioptric concave lens to the same distance gives us the 6-dioptric effect.

When this is remembered it is readily seen that any measurement of refraction by strong lenses is utterly untrustworthy unless the distance of the lens from the eye is taken into account; and if it is taken into account, any additional intermediate lenses are quite unnecessary. The above series is sufficient for the direct method in all cases except the very highest myopia, for which the expert ophthalmoscopist is apt to resort to the indirect method as more satisfactory.

To one accustomed to using a disc ophthalmoscope the arrangement of lenses as here in slides will at first seem awkward and confusing, but to one who begins with this instrument, or who has already used an instrument in which the lenses are so placed, it is especially convenient. The convex lenses are all in the back slide, the concaves in the front. One can be used alone, or both slides can be moved at once by the tip of the same forefinger, according to the lens required.

In the focus of the mirror, the size of the sight hole, the blacking of it, the proportioning of the instrument, and its mechanical execution, it is equal to the best ophthalmoscopes now used. It is made by Mr. D. V. Brown, of Philadelphia.

Since this is not my first attempt at the modi-

fication of the ophthalmoscope, and another instrument has my name associated with it, perhaps it will prevent confusion if I exercise the right of naming this. And with the idea of giving it a name that shall by a single word indicate the idea of its design for general use, I shall call it the polyclinic ophthalmoscope.

MISCELLANY.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.—Preliminary announcement of the programme for the seventeenth annual session of the Mississippi Valley Medical Association, to be held in St. Louis, October 14th, 15th and 16th, 1891.

1. "The Toxic Effect of Tobacco Vapor; with Report of Cases." W. Carroll Chapman, M.D., Louisville, Ky.
2. "The Management of Chronic Diseases." S. Baruch, M.D., New York, N. Y.
3. "The Ethics of Curing Consumption and other Chronic Diseases." John Ashburton Cutter, M.D., New York, N. Y.
4. "The Treatment of Typhoid Fever." Robert C. Kenner, M.D., Louisville, Ky.
5. "The Carbolates." William F. Waugh, M.D., Philadelphia, Pa.
6. "On Degenerative Processes in the Spinal Cord, Consequent upon Constitutional Diseases." Hugo Summa, M.D., St. Louis, Mo.
7. "Iliac Indigestion—Intestinal Dyspepsia—and its Treatment by Antiseptic Agents." Frank Woodbury, M.D., Philadelphia, Pa.
8. "The Influence of Graveyards on Public Health." J. W. Carhart, M.D., Lampasas, Texas.
9. "Rheumatism and Gout in their Casual Relation to Eczema; their Management." A. H. Ohman-Dumesnil, M.D., St. Louis, Mo.
10. "The Value of Epilation as a Dermato-Therapeutic Measure." Joseph Zeissler, M.D., Chicago, Ill.
11. "Gradation of Lenses." Dudley S. Reynolds, M.D., Louisville, Ky.
12. "The Influence of Alcohol on Vision." Francis Dowling, M.D., Ciuciunati, O.
13. "Tobacco and Insanity." Ludwig Bremer, M.D., St. Louis, Mo.
14. "The Present Aspect of Cerebral Surgery." Landon Carter Gray, M.D., New York, N. Y.
15. "Forensic Aspect of Bruises and Fractures in the Insane." J. G. Kiernan, M.D., Chicago, Ill.
16. "Amputation of the Scrotum, with report of a Case." B. Merrill Ricketts, M.D., Cincinnati, O.
17. "Observation on Urethral Stricture." G. Frank Lydston, M.D., Chicago, Ill.
18. "The Mechanical Element in Treatment of Compound Fracture." Warren B. Outten, M.D., St. Louis, Mo.
19. "A Report of a Case of Retention of Urine caused by Multiple Urethral Calculi." J. V. Prewitt, M.D., West Point, Ky.

20. "Some Observations on Rectal Surgery in Europe." Leon Strans, M.D., Louisville, Ky.

21. "A New Method of Diagnosing Obstruction in the Sigmoid Flexure." Jos. M. Mathews, M.D., Louisville, Ky.

22. "Pathology and Surgical Treatment of the so-called Strumous Inguinal Lymphadenitis." L. T. Riesmeyer, M.D., St. Louis, Mo.

23. "The Treatment of Gonorrhœa." E. C. Underwood, M.D., Louisville, Ky.

24. "Extirpation of the Thyroid, with Report of Case." Emory Lanphear, M.D., Kansas City, Mo.

25. "Are Conservative Amputations always in the Interest of the Patient?" Charles Truax, Chicago, Ill.

26. "Sarcoma of the Dorso-Scapular Region—Operation—Recovery." Geo. N. Lowe, M.D., Randall, Kansas.

27. "Mouth Breathing." Eric E. Sattler, M.D., Cincinnati, Ohio.

28. "Empyema of the Superior Maxillary Antrum, with only Nasal Symptoms." Hal Foster, M.D., Kansas City, Mo.

29. "A Superior Remedy for Nasal Catarrh; Campho-Menthol." Seth S. Bishop, M.D., Chicago, Ill.

30. "A Case of Reflex Aphonia; Demonstrated to be due to Pressure of the Middle Turbinate against the Septum Nasi." Hanau W. Loeb, M.D., St. Louis, Mo.

31. "Importance of Recognizing a Temporary Rachitic Condition in Infants." John A. Larabee, M.D., Louisville, Ky.

32. "A Pathological Study of Pelvic Inflammation in Women." Wm. Warren Potter, M.D., Buffalo, N. Y.

33. "Observation on the Management of Uterine Tumors." Chas. A. L. Reed, M.D., Cincinnati, Ohio.

34. "Complications Following Abdominal Section." Rufus B. Hall, M.D., Cincinnati, Ohio.

35. "Obstetric Dispensaries; their Management." L. A. Berger, M.D., Kansas City, Mo.

CONSTITUTION AND BY-LAWS OF THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Name.

ARTICLE I. This Association shall be known as the Mississippi Valley Medical Association.

Object.

ART. II. The objects of this Association are to foster, advance and disseminate medical knowledge; to uphold the honor and maintain the dignity of the medical profession.

Membership.

ART. III. Membership in this Association shall be limited to those members of the profession of medicine who acknowledge allegiance to the American Medical Association by signing its Code of Ethics. No individual who shall be under sentence of expulsion, suspension or disability from any recognized State, County, District or Local Medical Society, shall be eligible to membership in this Association until said disability shall have been removed. All applications for membership shall be referred to the Committee on Credentials. The annual dues shall be \$3, payable in advance.

Meetings.

ART. IV. The regular meetings of this Association shall be held annually. The place, with the time of meeting for each successive year, shall be determined by a vote of the Association.

Officers.

ART. V. The officers of this Association shall be a President, two Vice-Presidents, a Permanent Secretary, Treasurer, an Executive Committee consisting of the President, Vice-Presidents, Permanent Secretary, Treasurer, and the Chairman of the Committee of Arrangements; a Committee on Credentials consisting of five members, who may call to their assistance one member from each State represented at the meetings; a Judicial Council consisting of seven members, three of whom shall serve one year, and four for two years alternately. A Committee on Nominations which shall consist of one member from each State represented, shall be selected by the President on the second day of each annual meeting. It shall meet and nominate officers for the ensuing year, all of whom shall be elected on the last day of the annual meeting.

Duties of Officers—President.

The President shall preside at the meetings of the Association, and perform such other duties as parliamentary usage and the vote of the Society may require.

Vice-President.

The Senior Vice-President, or in his absence a Junior Vice-President, shall assist the President in the performance of his duties, and in the absence of the latter, or at his request, shall officiate in his place.

Permanent Secretary.

It shall be the duty of the Secretary to keep a list of the members of this Association with their addresses, to give notice of the meetings of the Association, to keep a record of its proceedings, to conduct its business correspondence, and perform such other duties as may be required.

Assistant Secretary.

It shall be the duty of the Assistant Secretary to assist the Secretary in the performance of his duties, and in the absence of the latter, those duties shall devolve upon him.

Treasurer.

It shall be the duty of the Treasurer to receive and disburse all moneys belonging to the Association. He shall pay out no money except on warrants signed by the presiding officer.

Committee of Arrangements.

The Chairman of the Committee of Arrangements may choose as many assistants as he may deem best, and appoint an assistant secretary, besides making all arrangements for annual meetings.

Changes in the Constitution.

ART. VI. This Constitution shall not be altered or amended, except the proposed alteration or amendment be first read on two consecutive days of a regular annual session of the Association and receive the approval of a three-fourths vote of all members present.

BY-LAWS.

ARTICLE I. The annual session shall be called to order by the Chairman of the Committee of Arrangements. The President on taking the chair shall call for the reading of the minutes of the previous meeting, and on the morning of each succeeding day of the annual session the following order of business shall be observed after the reading of the minutes.

1. Announcements of the Committee of Arrangements.
2. Report of the Secretary.
3. Communications from other Societies.
4. Reports of Committees. They shall be called in the following order. Committee on Credentials; Executive Committee; Judicial Council; Committee on Nomination during morning session of last day only.

ARTICLE II.

1. The provisions of Article I of these By-laws shall apply to the first thirty minutes of each morning session.
2. No essay or report shall be permitted to occupy more than twenty minutes without consent of the Committee of Arrangements.
3. Discussion of papers or reports presented shall be limited to ten minutes for each speaker and no member shall speak a second time except with the unanimous consent of the Association.
4. No essay, report or other communication presented to this Association shall be published in any but the

regular medical journals without the consent of the Executive Committee.

5. All questions of debate shall be decided in accordance with Cushing's manual of parliamentary law.

ARTICLE III.

1. All questions of ethics and differences between members shall be referred without debate to the Judicial Council whose report shall be final.
2. All questions of eligibility for membership shall be determined by the Committee on Credentials.
3. No person shall be allowed to participate in the deliberations of this Association who has not registered as a member and paid all dues.

ARTICLE IV.

These by-laws may be amended by a two-thirds vote of all the members present, provided the proposed amendment shall be made in writing and read aloud to the Association on two consecutive days at any annual meeting.

INVITED TO ATTEND THE UNVEILING.—The Secretary of the Illinois Army and Navy Medical Association has issued a call for the association to meet at the Grand Pacific Hotel, Chicago, the morning of Oct. 7 to participate in the ceremonies incident to the unveiling of the Grant monument. The invitation is also extended to all the medical men who served with the army and navy during the war to meet with the Illinois Association.

WANTED.—No. 4, vol. iii, July 26, 1884. Nos. 2 and 3, vol. xvi, Jan. 10 and 17, 1891. No. 3, vol. xvii, July 18, 1891. Will pay a liberal price for a few copies of each of the above numbers. Address this office.

LECTURES ON DISEASES OF THE URINARY APPARATUS are to be delivered by Dr. J. W. S. Gouley every Tuesday at 8:30 P.M., at the Mott Memorial Hall 64 Madison avenue.

These lectures, supplemented by clinics at Bellevue Hospital every Saturday at 3 P.M., will be free to the profession and students of medicine.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from September 12, 1891, to September 18, 1891.

Asst. Surgeon Louis W. Crampton, U. S. A., is relieved from duty at Ft. Sheridan, Ill., and ordered for duty at Ft. Townsend, Washington, relieving Asst. Surgeon James C. Worthington, U. S. A. Asst. Surgeon Worthington, on being relieved, is ordered to Ft. Thomas, Ky., for duty at that station, relieving Asst. Surgeon Geo. M. Wells, U. S. A. Asst. Surgeon Wells, on being relieved from temporary duty at Ft. Thomas, Ky., is ordered to San Carlos, Ariz., for duty.

Asst. Surgeon Geo. M. Wells, U. S. A., relieved from duty at Columbus Bks., O., and ordered to Ft. Thomas, Ky., for temporary duty, relieving Asst. Surgeon Henry I. Raymond, U. S. A. Asst. Surgeon Raymond, on being relieved, will report to the commanding officer, Ft. Robinson, Neb., for duty at that station.

Surgeon Charles L. Heizmann, U. S. A., is relieved from duty at Ft. Clark, Tex., and ordered to Ft. Douglas, Utah, relieving Surgeon William D. Wolverton, U. S. A., who, upon being relieved, will proceed to Ft. Schuyler, N. Y., and report for duty at that station.

Col. Edward P. Vollum, Chief Medical Purveyor U. S. A., retirement from active service is announced. S. O., 211, A. G. O., Washington, September 11, 1891.

Surgeon David L. Huntington, U. S. A., leave of absence extended to include September 30, 1891.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending September 19, 1891.

Medical Inspector A. A. Hochling, ordered as member of Medical Examining Boards.

Surgeon G. E. H. Harmon, ordered to the U. S. S. "Yorktown."

Surgeon Jno. C. Boyd, detached from the U. S. S. "Yorktown" and granted leave.

Medical Director F. L. DuBois, detached from Navy Yard, Portsmouth, N. H., and wait orders.

Surgeon J. G. Ayers, detached from U. S. S. "Wabash," and to Navy Yard, Portsmouth, N. H.

P. A. Surgeon F. J. B. Cordeiro, ordered to the U. S. S. "Wabash."

P. A. Surgeon O. D. Norton, ordered to the U. S. S. "Petrel."

P. A. Surgeon E. H. Marsteller, detached from U. S. S. "Petrel," and granted leave.

Surgeon Jno. H. Hall, ordered to appear before Retiring Board.

No. 14.

ADDRESSES.

THE PRESIDENT'S ADDRESS.

Delivered at the Annual Meeting of the Congress of American Physicians and Surgeons, Washington, D. C., September 23-25, 1891.

BY CLAUDIUS H. MASTIN, M.D.,
OF MOBILE, ALA.

Fellows of the American Surgical Association:

At your last meeting, in May, 1890, you selected me to be your presiding officer at this session; a session of especial interest, because it is the occasion when the several special Associations conjointly assemble to constitute the Congress of American Physicians and Surgeons.

Thoroughly appreciating the importance of the trust, and acknowledging the very great honor you have done me, I embrace the first opportunity which has presented, to thank you for this generous manifestation of your confidence and esteem.

It now becomes my pleasing duty to welcome you, together with our distinguished *confrères* from abroad who have honored us with their presence, to this, the beautiful capital city of this great, growing and prosperous Republic; a city surpassing in beauty and rivaling in grandeur the older and more favored capitals of the Old World; noted, both at home and abroad, for its intellectual and scientific advances, it is to become in the not distant future the centre of the science, the literature and the art of the Western hemisphere, as it is, even now, the political pivot around which revolve more than sixty millions of freemen! It is here that the Congress of American Physicians and Surgeons holds its triennial sessions, and it is the home of this Association. It is to this and to these that I bid you a thrice hearty welcome!

Since the organization of this Association, a body having for its object the advancement of the science and the art of surgery, a decade has passed away, and with the opening of this session a new epoch in the history of the American Surgical Association begins. It therefore is a fitting time to take a retrospective view of our history, to congratulate ourselves upon the auspicious present, and linger for a moment in the contemplation of the future. This I conceive to be a more

appropriate theme for the occasion, than for me to weary your patience with a scientific dissertation—especially so, since the efficient committee charged with the preparation of the programme, has laid before you a feast rich in this particular.

It was in May, 1879, during the meeting of the American Medical Association, then in session at Atlanta, Ga., that the founder of this Association called around him a few selected friends, and disclosed to them a plan—which for many years had been a cherished object of his ambition—that of organizing an Association which should bear a National name, and embody in one harmonious whole the surgical talent, experience and wisdom of this great country. The question was pertinently asked, "What need is there of such an organization, since the country is full of all kinds of medical societies?" It was argued that the Surgical Section of the American Medical Association offered all the requirements necessary, and that the organization of a special Association, having for its object the advancement of the science and art of surgery, was not called for, and would be looked upon as having for its purpose only the injury of the old Association, striking, as it were, a direct blow at the Surgical Section.

With the far-seeing wisdom characteristic of the man, he thought differently, and believed the effect would be directly the opposite. He believed and said that the time had come in the history of medical and surgical affairs in America, when such an organization was a necessity, and should be created. He disclaimed then, as we do now, any opposition whatever to the old Association, and he asserted that it was impossible for any new organization to be in the least detrimental to it.

From the day on which the old Association was organized, he had been an active and influential member; once its President; often a contributor to its volume of Transactions; governed by its Code of Ethics. He remained true and loyal to all its requirements, as evidenced by the fact that when, on his death-bed, he was asked by a friend "what message he desired to send to the American Medical Association?" he replied, "Give them my love." Also the very last paper he ever wrote was being read in that Associa-

tion, during its session of 1884, on the same day that he died.

It is my honest conviction that neither our illustrious founder, nor any Fellow of this Association, has ever entertained any sentiments of opposition to the old Association. On the contrary, as American physicians and surgeons, we feel an honest pride in the work that she has done, and we are the last who would obstruct the progress of an Association which is so necessary to the professional interests of the country at large. We are free to admit, however, that we know the time has come in the history of medical affairs in this country, when the special branches of the profession must be separately recognized. Not that they should be divided into departments having no reliance one upon another, but as integral parts of a great and undivided profession, they should be so organized as to stand "distinct as the billows, yet one as the sea." The Congress of American Physicians and Surgeons is simply a development of this principle.

But he was building even better than he knew, and now, the ten years which have passed so rapidly away have answered the question, "What need is there of such an organization?" The first regular meeting of this Association held for the transaction of scientific and practical work, took place at Coney Island, in the State of New York, in the September of 1881; a meeting which was attended by a very small number of its Fellows, yet the character of the work which was done was useful, and laid the foundation of the triumphant success which has since been attained.

Nomadic in its beginning, the next meeting was in the city of Philadelphia, on the 31st day of May and the 1st and 2d days of June, in the year 1882. At this session a fellowship of only twenty-five were present, but the work was practical, full of zeal, and showed that the Association was to become, in the not distant future, an altar upon which would annually be laid valuable contributions to surgical science, and the world said, even at that time, its membership were destined soon to become earnest and zealous laborers in the interest of human progress and human suffering.

The third session was called together in the city of Cincinnati, on the 31st of May, 1883, and forty Fellows, all told, constituted its full strength. Its first volume of Transactions, which was published after that meeting, attests the amount and the value of the work which was accomplished. Everything then seemed to foreshadow a bright future, and nothing transpired to dim the occasion, save the absolute refusal of our beloved founder, and President, to accept a re-election to office.

That great man, the Nestor of modern American surgery, the founder and the cherished idol of this Association, Samuel David Gross, standing without peer and without reproach, held that

he had no preëmption right to office, and contended that he had occupied it long enough. He thought that his re-election would be at variance with the genius of our republican institutions and the habits of the American people. He believed that rotation in office should be the order of the day, not only among politicians but among scientists and professional men. He felt that his highest ambition as respected this Association had been accomplished. He appreciated clearly that the work which he began was exceeding his most sanguine expectations, and was surely destined to pass into history. We knew that we were losing the guiding hand of a great pilot, and we were loth to permit him to leave the helm of office to serve in the ranks. In the language of a gifted Fellow of this Association: "had the constitution conferred upon us the power, we would have put on him the royal purple, and hailing him chief among all, have bid him wear it for life." But he was inflexible, and that meeting was the last he ever attended. Those of us who were present on the closing day of that session can never forget the trembling words and tearful eyes when he said: "Now that I am about to retire from the discharge of these duties, I feel sure that the interests of the Association will be perfectly safe in your hands, and in the hands of my distinguished successor. I have no greater ambition than to live in your affection and esteem, and to witness the ever-increasing prosperity of this Association. Its success is closely associated with the remainder of my life. I believe that we have an Association which is destined to become a power for good in the land; and when I am dead and gone you will not, I am sure, relax in your efforts to make it what its founder intended it should be—a great and lasting institution. God bless you, gentlemen, in all the relations of life, and may you ever be faithful to the interests of the profession and the Code of Ethics in connection with which we have carried on our work."

Gentlemen, these were the farewell words of an old patriarch to his children, and they should sink deep into your memories, for they were spoken by a truly great man; one of those who are "born beneath the aspect of a bright-eyed star, and whose triumphant adamant of soul is but the fixed persuasion of success."

In less than one short year from that day, he rounded up his great life and rested!

The future was before us. When from Cincinnati the Association took a new departure, and, under the leadership of that venerable and gifted surgeon, Edward Mott Moore, we next assembled here, in the City of Washington, on the 30th day of April, 1884. From that time it can truly be said "we have had a local habitation and a name." Time does not permit me to enter into the details of our annual sessions, which have

been held in this city each spring, nor to mention the interest and enthusiasm of our Fellows, which have made these reunions so pleasant and instructive as they have been. Suffice it to say, our successive and successful meetings from then till now, under the guiding hands of Moore and Briggs, Gunn and McGuire, Agnew, Cheever and Yandell, have gradually passed from small beginnings to the present prosperous and renowned Association which has assembled here to-day.

When this Association was first organized, anæsthesia had but enlarged the domain of surgery. To-day antiseptis, followed by asepsis, has emboldened the surgeon to undertake and perform operations hitherto deemed impossible.

Whilst anæsthesia had measurably lessened shock, antiseptis with asepsis have gone a step beyond, and done much toward the prevention of septic results, thus making the possibilities of surgery even greater.

In the last decade, the rapid and steady advances of the chirurgic art have far outstripped all other departments of the profession; and with the constant and seemingly never-ending improvements now going on in all the branches; the discoveries in chemistry, with the consequent additions to our *materia medica*; the revelations of the microscope, leading to a proper understanding of pathological lesions, and the clearing up of doubtful points in physiology, together with many new precisions in the study of all the branches of medicine, have enlarged the vista before us, so no one can predict the limitations which may not be reached in the next ten years. It was but yesterday when the closed cavities of the body were held as sacred—the organs within the abdomen, the lungs and heart within the thorax, the brain and spinal cord cased by the skull and vertebral column, were each surrounded by a dead-line which none dared to cross. To-day, they have each become the legitimate field into which the surgeon has carried his knife.

The Old World and the New World, shoulder to shoulder, have been busily engaged in blazing out the pathway from art to science. If our friends from abroad should ask what has been doing here in America, and what hand has this Association taken in the good work? I could tell them, if it would not be considered invidious for me to use names, what our Fellows have been doing in abdominal surgery; their operations upon all the organs contained in the abdomen; their improvements in the treatment of gunshot and other wounds of the intestines; their work done in the thorax, and show them that the brilliant achievements of Horsley, Godlee, Macewen and others across the Atlantic, in brain surgery, have been reproduced here with equal success. Even were it proper to do so, time would not permit me to enter into details of the brilliant work which has been successfully done by the

Fellows of this Association in all the regions of the body, both external and internal. Suffice it to say, American surgeons have not been idle nor non-progressive, and their work has been placed on record.

Whilst this Association has been advancing the cause of surgery, and doing much to alleviate the distress of suffering humanity, it is sad to have to relate that death has been busy in our ranks, and that some of our best and most eminent Fellows, even in the midst of their labors and the height of their usefulness, have fallen in their harvest and been gathered to their fathers. Their loss has proved a serious and irreparable one to the Association, no less than to the country.

Since our organization we have been called to mourn the loss of twenty-one of our brothers, among whom we chronicle the death of two ex-Presidents, four ex-Vice-Presidents, four members of the Council, and seven of our Honorary Fellows. Only a very small number have resigned; whilst on the other hand, the applications for membership have vastly exceeded the number of admissions.

It is indeed gratifying to know that those who have fallen from our midst were earnest and zealous laborers in the cause of surgery, and enthusiastic in their efforts to advance the best interests of this Association.

Now when we pause to drop a tear of sympathy and sorrow upon the greensward which covers them, we are solaced with the recollection of their many virtues, and the assurance that although they have passed to the great majority, they had reached eminence in their profession, and left behind them records of well-spent and useful lives. They live honored in our memories.

It is proper to mention that much of the success of this Association has been due to the indefatigable labors of our efficient secretary, who from the date of our organization to the present time has been distinguished for the unwearying and unselfish zeal which he has shown in the duties of his office, and he deserves the highest commendation for the work which he has accomplished. No less are we indebted to the recorder of the Association for his labors, for to him especially is due the editing and publication of the beautiful volumes of transactions which have followed our annual meetings. Lastly, though not least, all praise should be accorded to the Fellows themselves for their zealous coöperation in all the labors of our annual sessions, and their successful endeavors to make the Association what its founders intended it should be, "A great and lasting institution."

During the ten years which have passed so rapidly away, it will be observed that the Association has steadily advanced in prosperity and usefulness, winning for itself an honorable station among the learned societies of the country,

and claiming the admiration of those of the old world. Its volumes of yearly transactions are replete with valuable scientific productions worthy of their authors, and honorable alike to the Association and the Nation. Its membership comprising the leading surgical talent of the land, has fostered an *esprit de corps*, such as is to be found only among refined and agreeable gentlemen.

Bound together as we have been for ten years, new acquaintances have been made and they have ripened into friendships, old ones have been renewed and cemented; and to-day the American Surgical Association stands before the world an united brotherhood inspired with one sentiment, that of doing good to suffering humanity and advancing that department of the healing art to which they have consecrated their lives.

In this connection, a justifiable pride compels me thus publicly to say, from the day of our organization to the present hour, in all our public and private relations; in our intercourse with each other; in our scientific discussions and social reunions, there has not been one single occurrence, one harsh word to mar the harmony of the occasion or disturb the friendship of its Fellows. Verily this is a record, strange and unusual in the history of medical associations and deserves more than a passing notice.

Such in brief, is the outline of our past, and whilst we have every cause to congratulate ourselves upon the successful termination of the decade we are leaving behind, it is still necessary that we should comprehend the importance of the trust which has been placed in our keeping by the founders of the Association.

Holding in our hands its spotless record, it is a happy privilege to be able to feel that we desire its history hereafter to be, but a just development of that which has gone before; so that the ever opening pages of its future may continue to be lighted, as they now are, by a bright reflection from its past. Now let us, here to-day, join hands around this family altar, and renew our vows to make her still greater than she is.

Before closing, I beg to be permitted to make a few suggestions which I trust will not be taken in the light of criticism of the past management of the Association.

First, I suggest that a business committee be provided, whose duty shall consist in the preparation for and arrangement of the scientific work of the meetings; such a committee duly authorized would relieve the president and secretary of much labor and responsibility, and the work which they would accomplish would better serve the interests of the Association than if left to the will and pleasure of the presiding officer.

At the session of 1886, a resolution having this end in view was offered as an amendment to the by-laws, and under the rule was laid over for

one year: it however, failed to secure the approval of the Fellows at the session of 1887, and was finally tabled. I now recommend that proper action be had to the effect that the resolution of 1886, be taken from the table and passed, so that the by-laws will require a committee composed of the president of the Association, its secretary and the recorder, together with the two senior members of the Council, to take charge of the preparation of the scientific work of the Association. Their duties should be to select such subjects for the regular essays as they deem best, and have the appointment of those Fellows to lead in the discussions of these papers as in their judgement they believe will serve the best interests of the meetings. It should be fully understood, however, that all volunteer papers be left to the option of the Fellows without the interference or control of the committee.

Although there has not been as yet, any constitutional provision for such a committee, still we have had during the present session and the one immediately preceding it, the benefit of an unofficial committee which has been of vast service in the organization of the meetings, and I now take this opportunity to acknowledge my own indebtedness to them for the very valuable assistance which they have rendered to me in preparing the work of the present session.

Secondly. I suggest that our present limit of fellowship be increased from one hundred to one hundred and fifty. I am induced to make this suggestion entirely in view of the vast extent of our country and the large number of young surgeons throughout its wide domain, who are rapidly rising to eminence in their chosen branch. When this Association was first organized, it was then the part of wisdom that our restrictions should be limited, and our membership confined to a small select body of workers. Now the situation is different, and having passed the stage of adolescence we are prepared to extend our field of operations, and in doing so it is but proper that we should remove the obstruction of exclusiveness; with our present limit of membership we are arrogating to ourselves too much when we claim to be the representative body of American surgeons.

In this, I do not desire to be misunderstood, because I would urge that all due vigilance be exercised in the admission of new Fellows; the present high standing of the Association must be preserved. Age, scientific attainments, with surgical experience and general culture should be the necessary prerequisite for admission.

We have set up for ourselves a high standard and we can maintain it only by guarding our portals against unworthy applicants. Besides protecting ourselves, we must remember that each one of the conjoint Association is in honor bound to stand sentinel at the doors of the Con-

gress, and as membership in that body can only be had by virtue of fellowship in one or another of the special societies, it is a duty which each one owes to the other to protect the purity of the confederation.

It should be our aim and attainment to make the Association the representative body of surgical science in America; and to accomplish this most desirable end genuine ability and solid work must be the indispensable qualifications for admission; and continued scientific activity, the recognized duty of membership. With such a standard before the world, it will soon become a high and coveted honor to be known as a Fellow of the American Surgical Association.

Now leaving the larger views, I have expressed for a subject which should be nearer and dearer to us all, though not on that account a narrower sentiment, I ask your indulgence only a few moments longer.

It is well known to the world at large, no less than to the profession of which he was an honored member, that Samuel David Gross stood first in the foremost rank in his chosen branch of the profession, and that the high position to which American surgery has attained all over the world, is largely due to his example and his teachings.

Since he has passed away and his life work gone into history, we fully appreciate his real worth, and therefore it is his friends and admirers have been inspired to erect a monument to his memory. Such a monument as will bear testimony of their gratitude and be in the future an incentive to those who are to come after us, to like noble deeds. To further this praiseworthy enterprise, I suggest that a committee from this Association be appointed to confer with the friends and admirers of Dr. Gross and with the medical profession of the whole country to determine the best method to be adopted to secure the requisite amount for the erection of a monument either of marble or of bronze.

Such tributes to the memory of distinguished men are common both in this country and abroad; and when in our own profession, a man is found who has done so much to adorn it, it is meet that we should show to the world our appreciation of his work.

Dr. Gross was probably more widely known and appreciated than any American Surgeon of recent years, and when we remember that thousands of his pupils are scattered throughout the whole of America, men who sat under his teaching and who still retain of him the warmest memories, it is not expecting too much when we feel assured of their coöperation in raising speedily and without difficulty the requisite amount for the completion of such a monument.

I do not suggest that this work be done by the Association exclusively, nor would I advise it if

it could be. I would prefer to see it done by the profession of the entire country, because Dr. Gross belonged to no exclusive faction but was a member of the profession at large. It is proper, however, that this Association take the initiative in beginning the monument, and I feel assured that there will not be the least doubt as to the successful issue of the undertaking.

If any man in our profession has merited such a tribute, sure Dr. Gross was most eminently entitled to it; for he was a man animated by fervent attachment to the science and practice of his profession, and it was the duty of his life to augment and exemplify the resources of surgery; and by most assiduous and successful application of his time and his talents, his name has become known and honored, not only in his own country but in every land.

Appreciated and honored as he has been in life, let us now, since he is dead, build to his memory such a monument as will bear witness in after years to the estimate in which the profession of to-day holds its distinguished members.

If it were asked of me where such a statue should be erected, I would answer not at Easton, in the State of Pennsylvania, the place of his birth, neither at Cincinnati or Louisville, where he laid the foundations of his future greatness, nor even in the city of Philadelphia where that greatness culminated in all its grandeur; but here in the city of Washington, the capital of the country, which claims him as her own. His name and fame are a sacred heritage to the country at large, and to the profession he loved so well. Then, here in this beautiful city, amid these verdant parks and hard by these massive piles of classic architecture, let us place it among these statues, emblems of a nation's gratitude to her illustrious dead, her statesmen, her warriors, her jurists, her philosophers. Build it here, so that in the ages to come, when the youth of the land make their pilgrimages hither, they will behold the monument which their forefathers reared to commemorate the life and character of her greatest surgeon. It will teach them to emulate his example.

Thanking you for your kind attention we shall now proceed with the regular business of the Association.

TREATMENT OF THE VOMITING OF PREGNANCY.—The *Deutsche medicinische Wochenschrift* recommends the following treatment of pregnancy:

NASAL CYSTOMATA—REPORT OF TWO CASES.

Read before the Section of Laryngology, Washington Meeting American Medical Association, May, 1891.

BY C. W. RICHARDSON, M.D.,
OF WASHINGTON, D. C.

Cystic tumors involving the mucous membrane of the nasal passages, *i. e.*, true retention cysts, are very rare, if one must form his opinion from the meagre number of reported cases, and the treatment received by this subject—or not received—in most of the classical works upon rhinology. Many of our standard authorities make no mention of this subject, either under a special caption, or under the general subject of mucous polyps. Bosworth in his great work upon the nose devotes one page and a half to the consideration of this neoplasm. Watson and Sajous devote a small space to the consideration of this growth, both referring to its rarity. Wagner reports Leffert's case *in extenso*.

Seiler, in a few lines, speaks of having seen this form of neoplasm and describes it "as large sessile cysts filled with the watery mucous and springing from lower border of inferior turbinate." McKenzie, Brown, Greville McDonald, Cohen, Ingals, Sturck, Votolini, Schech, Bressen and Moldenhauer make no mention of the subject. In the literature which was accessible to me I found reported four undoubted cases of nasal cystomata, two of which were made by British and two by American observers. To Dr. George Johnson belongs the honor of having reported the first case, which is delineated in a most excellent manner, and with a most exact drawing, in the *London Medical Circular* for 1864. The other observers are Lefferts,¹ E. Fletcher Ingals,² and Reginald Horsley.³

Spencer Watson reports a case, under this heading, in the proceedings of the Medical Society of London, but in its description he shows it to be rather a cystically degenerated mucous polypus than a true retention cyst. In the second edition of his work upon the nose he acknowledges this fact in the following lines:

"In the proceedings of the Medical Society of London a case of mine is recorded which might be more properly described as a cyst-bearing polypus than as a cyst."

Carl Seiler, in referring to the report of Leffert's case, in the *Philadelphia Medical Times*, refers to having seen three cases, and reports another, a cystically degenerated fibroid growth. The latter could hardly be classified under this grouping. It is important to bear in mind that there is a marked difference between a true re-

tention cyst and a cyst formed by the degeneration of a solid growth. As Watson says, "It is not uncommon to meet with small adenomata which have been undergoing cystic degeneration," and the same is true of gelatinous polypus. With Johnson's, Lefferts', Ingals' and Horsley's cases, which are reported in full, and Seiler's three, of which he only makes mention, we have, so far, reported seven of these interesting neoplasms.

The pathological history of these growths, within the nasal cavity, cannot differ from that of true retention cysts occurring upon mucous surfaces in general; being formed from retention of the secretion within the normal glands of the mucosa. The pressure of the retained secretion becoming great, an abnormal activity takes place within the gland, and it slowly or rapidly becomes transformed into a true cystic neoplasm. The seat of attachment of these growths is, as described by all authorities and as present in my two cases, on the outer wall of the nasal cavities, between the middle and inferior turbinated bodies, about 2 centimetres anterior to the mouth of the Eustachian tube. In four of the cases they appeared in the right, and in two in the left nasal cavities. They are pyriform in shape, of a grayish white color, resembling very much the ordinary gelatinous polypus. They have been observed at all ages, from the twentieth to the fiftieth year of life.

The symptomatology of this condition does not differ from that due to other obstructive diseases of the nasal fossæ. More or less catarrhal secretion is always present, with various degrees of obstruction to nasal respiration through affected passage. Owing to the valvular-like action of the growth, obstructing the post-nasal orifice, expiration is more difficult than inspiration. During respiration the patient feels a to and fro movement in nasal cavity, due to oscillation in growth produced by the impact of the incoming and outgoing column of air. Voice shows usual want of nasal character. Pain is usually absent; but there is always noted a disagreeable sense of fulness upon affected side, as though something foreign were in pharynx. Nasal reflexes may or may not be present. In Horsley's case asthma was a very pronounced symptom, which was relieved by removal of growth. By inspection, through anterior nares, at the posterior portion of the passage can be seen a prominent reflex, moving during respiration. It is only through posterior rhinoscopy that the characteristic outlines of the growth can be observed. The tumor is seen as a large pyriform mass of a grayish white color, having very much the appearance of a mucous polypus, filling out more or less completely one post-nasal orifice. Ramifying over surface of neoplasm are numerous small blood-vessels. On sounding with a probe, it will be noted that the mass is firm,

not pitting upon pressure, or presenting that soft, elastic feel of gelatinous growths.

Diagnosis.—The diagnosis of this condition should present no difficulty to the cautious observer. We have the evidences of obstructive nasal catarrh, unilateral in its character, gradual in its onset, and of varying time as to duration. The voice is markedly altered; and to that degree only present in complete obstruction of nasal cavities, or in interference with functions of velum palati. Direct inspection by anterior and posterior rhinoscopy shows existence of polypoid-like, pyriform neoplasms, projecting from nasal into pharyngeal cavity.

The differential diagnosis from mucous polypus is very simple. These gelatinous growths never spring from the seat of attachment of cystic bodies; they rarely ever grow singly, and before reaching the size of these bodies would have many companions; they are soft, indenting to the probe, never giving that firm, solid-like impression imparted by the cystic neoplasm.

From fibroid, sarcomatous and carcinomatous growths, the differential is so simple as not to require description. Is very rare and presents the characteristic pulsation.

Prognosis.—Removal is always attended with absolute relief. No recurrence has ever been noted.

Treatment.—The treatment to be adopted is that of removal of the neoplasm. The simplest method of removal, and the one likely to cause the patient the least discomfiture, would be the preliminary tapping of the cyst, and evacuation of its contents. The empty sac could then be blown forward into the nasal cavity by the patient, where it could readily be grasped by forceps, over which a snare should be threaded and the mass easily enucleated.

This proceeding had to be resorted to in both of my cases, although, I am sorry to say, after I had given them considerable discomfiture by attempting to remove the growth in its entirety.

Cases.—My first case came under my observation November 24, 1889. The patient was a young Hungarian, thirty-two years of age. For ten months past he had noticed a gradually increasing obstruction of right nasal cavity, which had, during the past two months, become almost absolute. He had no pain, although a feeling of discomfort, as though something foreign existed in nasal and pharyngeal cavities, was always present. The alteration of his voice was the condition that annoyed him the most. He is a professor of languages, and it was necessary that his voice should be good. During inspiration, a small amount of air could be drawn through cavity, but expiration was impossible. Left nasal cavity was clear. There was some post-nasal secretion. On examination by anterior rhinoscopy, there was nothing observed in anterior

portion of cavity to give any clue as to cause of interference with the normal function of this organ, but deep within the passage could be seen a reflex, indicating the probable existence of a polypoid growth. In the upper portion of pharyngeal cavity was observed a large pyriform, polypoid looking growth, bearing all the resemblance to a true mucous polypus. The base of the growth could only be seen, as it nearly filled out the whole pharyngeal cavity, above the soft palate. Digital exploration demonstrated the growth to be limited largely to the right side, with its seat of attachment within the nasal cavity. It was dense, non-elastic; not presenting the soft, gelatinous feeling of a mucous polypus. I was lost for a diagnosis. Removal was attempted by snaring through the nose, but while adjusting loop over the growth, with finger in pharynx, the sac ruptured, and the contents, a clear serum, was evacuated; the relief was complete. The patient, while clearing his nasal cavity of serum, blew the sac forward, and it presented itself at anterior nares. Supposing the mass to be free from its attachment, I grasped it with a pair of forceps, tearing off the base, which is here represented. Finding that still some remained, I threaded a snare over a pair of forceps, again grasped the mass, and enucleated it from its attachment. I failed to make measurements, but the growth, which has now been immersed in alcohol for eighteen months, speaks for itself.

My second case presented all the symptoms of the first, above mentioned. The patient was a young man of twenty-three years of age, a lithographer by profession. Had noticed obstruction for six months. The growth was not so large as in former case. The diagnosis was made of cystomata, and growth removed with same mishaps as in former case. Dr. H. L. E. Johnson kindly assisted me in first case, and Dr. H. B. Deale in second.

LARYNGISMUS DUE TO A CONGENITAL VALVULAR FORMATION OF THE UPPER ORIFICE OF THE LARYNX.

Read in the Section of Laryngology and Otology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY J. H. BRYAN, M.D.,
OF WASHINGTON, D. C.

In this short communication it is my purpose to call attention only to that form of spasm of the infantile larynx due to a congenital valvular formation of the upper orifice of the larynx, a condition that is sometimes overlooked as a cause of noisy respiration in children.

In these cases there is a laryngismus of a mild variety, and as it is so very persistent, it is evident that it must depend upon some local cause. The

subjects of this condition may be perfectly healthy, showing no evidences of rickets or glandular enlargement—the most common causes of that severe form of laryngeal spasm known as laryngismus stridulous. There is no tendency to convulsions, and the respiration is noisy, or reedy, as described by some, being at times quite labored. The spasm is more persistent than in the severer forms of laryngismus, being present to some extent during sleep, and is greatly aggravated upon any excitement, such as sudden awaking from sleep, sudden change from a warm to a cold atmosphere, crying, change of position, dentition and gastro-intestinal disturbance.

According to Goodhart,¹ it was formerly supposed that at this stage of life, the larynx was too yielding, and that when a rush of air was produced by means of a deeper and more hurried breathing than usual, the air could not pass fast enough, and a noisy respiration was the result. From an observation made by Dr. Lees, an English physician, it appears to be due not so much to a yielding of the parts, as it is to a natural condition of them. He made an inspection of a case that died from other causes, and found that the epiglottis was excessively recurved in its vertical axis—"as if bent in half down its middle," thus bringing the ary-epiglottis folds almost in apposition, leaving a mere chink between them.

In 1878, J. Solis-Cohen² called attention to an allied, but much more serious condition, in which the epiglottis was abnormally long, and became incarcerated between the ary-epiglottis folds, causing suffocation. The two cases he reported terminated fatally.

Suckling, an English physician, in the *British Medical Journal* for December 15, 1890, reports one case in an infant 2 months old, and speaks of having observed this affection several times in very young children in the Children's Hospital, London.

Dr. Louis Starr, in a personal note concerning the case I herewith report, states that he has seen a number of cases showing the same congenital deformity, but in none were the symptoms so marked as in my case.

The prognosis of these cases is generally favorable, the difficulty with respiration passing off with the growth of the larynx. [In the way of treatment there is little that can be done, except to give tonics, and keep the child well nourished and free from all excitement.]

The following is the report of an interesting case, and illustrates well the condition I have just described:

In June, 1889, I was called to see a male child 9 months old, suffering from a spasm of the larynx that gave rise to a noisy respiration, and choking symptoms when nursing from the bottle.

The family physician informed me that when the child was 2 weeks old these symptoms were first observed, and they seemed to be increasing rather than decreasing as the child grew older. I was unable at this time to form any definite opinion as to the cause of the trouble, and it was not until I saw the case again at Oakland, Md., where I was called on account of his condition becoming much more aggravated, that I was able to assign any cause for the difficulty. At this time the respiration was noisy and could be heard at a distance of 40 feet or more, being at times distinctly spasmodic in character, and was as loud during sleep as in the waking state. When sleeping, the head was generally stretched back, so as to admit of the air passing in with as little resistance as possible. Examination showed no glandular enlargement, and no evidences of rickets. Other symptoms noted at this time were dilatation of the left pupil, sweating of the left side of the head and neck, phimosis with a very small preputial orifice, excessive irritability, and frequent eructations of undigested milk. It was then ascertained that the child's diet consisted of undiluted cow's milk.

Depressing the base of the tongue, the fauces were found to be congested, and the tonsils moderately enlarged. The epiglottis, as well as could be ascertained, was irregular in outline, and bent backward over the laryngeal cavity.

The spasm at times was so marked that I passed the index finger down to the upper laryngeal cavity, and pulled the epiglottis forward. After this manipulation, the child's respiration was natural for at least a week; but at the end of this period the spasm returned with its former severity.

This I believe to be an exaggerated case of infantile spasm of the larynx due to a binding of the epiglottis causing the ary-epiglottic folds to come almost in apposition, so that during inspiration there was a slight stridor produced. This difficulty with the respiration made a severe impression upon the central nervous system, which was greatly increased by the gastric irritation due to feeding the child with undiluted cow's milk, and also by that due to the phimosis.

The only treatment adopted was to dilute the milk, and to relieve the phimosis, which was done upon his return to Washington, by gradual dilatation. As soon as these sources of irritation were removed, the child commenced to improve as far as his general health was concerned, the respirations ceased to be spasmodic in character, and gradually became normal.

Another case that has recently come under my observation, was the 2 months old daughter of a professional friend. This child had the same characteristic breathing, but not to such a marked extent as in the first case.

No treatment was adopted, and in two months the difficulty had entirely disappeared.

MOUTH BREATHING NOT THE CAUSE OF CONTRACTED JAWS AND HIGH VAULT.

Read Before the Section of Laryngology and Otology, at the Forty-second Annual Meeting of the American Medical Association, at Washington, D. C., May, 1891.

BY EUGENE S. TALBOT, M.D., D.D.S.,
OF CHICAGO.

Mouth breathing was not known among the early races, the present pure races or modern uncivilized races, neither are deformities of the jaws and teeth. You will all admit that mouth breathing is becoming a very common occurrence among our own people, and so are also irregularities of the jaws and teeth. It stands to reason, then, that the causes which will produce the one must necessarily, in many cases, produce the other.

In an otherwise able article upon the subject of "The Influence of Adenoid Hypertrophy at the Vault of the Pharynx Upon the Development of the Hard Palate," read before the New York Odontological Society, November 19, 1890, by Dr. D. Bryson Delavan, the author speaks of mouth breathing as a cause. He says: "The mouth breathing habit compels the constant dropping of the lower jaw, which, hanging by the cheek from the superior maxilla, causes constant pressure upon the upper jaw. This produces flattening of the lateral alveolar arches and shortening of them, in consequence of which there is not sufficient space for the eruption of the canines when they are due, and they therefore grow forward."

Other authors mention that sleeping with the mouth open produces tension of the buccinator muscle, this causing the jaws to contract, and they suggest different theories by which this pressure brings about the peculiar form of deformity. There are also very able gentlemen (specialists) teachers in our medical colleges, who are constantly bringing this theory before the students as a cause. This teaching has a tendency to defeat scientific investigation in the direction of ascertaining the real causes of the true condition found in obstruction of the nasal passages by assuming to place the real fact, namely, mouth breathing, as the cause. The students take it for granted that this is the cause and the only cause for this condition.

Let us look at a few facts as they have been presented to me in the constant study of the deformities of the jaws and teeth for the past fourteen years; and you, gentlemen, shall be the judge whether mouth breathing has anything to do with contracted arches or not. In the first place, let us glance at the parts involved. The superior maxillary bones are united at the median line. The outer surfaces have upon their border an alveolar process. Gray speaks of these two structures as one bone, the superior maxillary bone; but from the function, structure and

position of the alveolar process in its relation to the maxillary bone proper, they should be described as separate and distinct bones. The maxillary bones proper are made up of dense compact tissue, and are so arranged as to resist force. The outer surface of the bone is fortified and supported by the malar process, which is situated midway between the maxillary process and the canine eminence at the first permanent molar. At the canine eminence we have the strong thick plate of bone extending from the bridge of the nose to the alæ, the mesial portion forming the outer surface of the nasal cavity. We also observe that the nasal septum is situated at the centre of the nares and is attached to the maxillary bone at and along the place of union of the two halves of the maxillary bone. If a saw was passed through from one canine fossa to the other we should see that it involved the strong pillar of bone which goes to make up the outer surface of the nasal cavity. This strong pillar of bone is situated just at the point of the permanent location of the cuspids; this, together with the nasal septum, form a strong support to the hard palate. The maxillary bones are for the attachment of muscles and the resistance of force in masticating food. The hard palate does not assume the normal shape until the twelfth year, or after the teeth are all in position. The vault may be high or low, ranging from one inch above the margin of the alveolar process, between the second bicuspid and first permanent molar (which is the highest vault I have seen) down to one-quarter of an inch from the same point, which is the lowest vault I have observed. In either case they are normal, each variety depending upon the shape of the bones of the head for its peculiar form. The alveolar process, on the other hand, is made up of soft cancellated structure, and is solely for the purpose of protecting the germs of the teeth before they have erupted, and it also supports the teeth after they are in place in the jaw. From the time the teeth make their first appearance until they are lost, the alveolar process has developed and been absorbed three distinct times. The alveolar process, then, being solely for the protection and support of the teeth, it stands to reason that the position and shape of the alveolar process depend upon the location of the teeth. The bone proper, therefore, as we shall see later, is not influenced to any great extent by the movement of the teeth. The buccinator muscle is composed of striated muscular fibres, and is therefore under the control of the will. It is penniform in shape. It has its origin and insertion along the body of the jaws, above the alveolar process on the upper jaw, and below the alveolar process on the lower. It extends from the first bicuspid tooth anteriorly to the wisdom tooth posteriorly. The centre of the muscle would therefore be in one direction on a

line with the grinding surface of the teeth, and in the other direction at the first permanent molar. Its function is for the purpose of compressing air in the act of blowing, whence its name is derived, and also for the purpose of carrying and holding the food under the teeth during mastication. There are many cases of contracted arches where mouth breathing does not exist. There are also many cases of normal arches where it does exist. As all are aware, mouth breathing frequently commences very early in life; contracted jaws, on the other hand, never commence to form until the seventh or eighth, and in most cases the tenth year, except in cases of monstrosities, or from traumatic causes. When these conditions exist they are wholly unlike the usual contracted arches and can be diagnosed at once, and therefore should not enter into this discussion. Contracted arches are of two kinds—V (Fig. 1) and saddle (Fig. 2)—all the other varieties being modifications and blendings of these two. It is apparent to every one that the cause which pro-

FIGURE 1.

duces the one does not produce the other. My observation has been that there are two-thirds more V and saddle-shaped arches among the low vaults than among the high vaults, taking $\frac{1.8-7}{3.2}$ of an inch as the average, but where one of these deformities exists with a high vault it is always more marked, for the reason that in the high vault the alveolar process is high and thin, and the teeth are more easily carried in one direction or the other, with very little resistance. In the V-shaped arch commencing at the first permanent molar, there is a gradual narrowing of the teeth and alveolar process toward the median line, where the incisors may reach a point or may stand in their normal position to each other. Invariably there is a protrusion of the teeth and alveolar process, and not the jaw. On the other hand, in the saddle-shaped arch the bicuspid are carried inward and the deformity is invariably situated between the first permanent molar and

the cuspid. Unlike the V-shaped variety the anterior teeth and alveolar process never protrude in this class of deformities. The contracted hard palate is always associated with the V-shaped variety, and in most cases extends backward to the second bicuspid. It is never seen with the saddle-shaped variety. The high vault is never seen in the first set of teeth, nor does it develop until the second set are all in place, which is at the twelfth year. The vault commences to slope slightly from the neck of the incisor until it reaches a line drawn across the roof of the mouth from the first right bicuspid to first left bicuspid, and then it gradually or abruptly slopes upward until a line is reached which is drawn across the jaw from the anterior surface of the opposite permanent molar. From this point posteriorly to the soft palate the dome is usually on a level; occasionally we see a slight depression and occasionally a slight elevation, but these are so slight as to escape notice unless one were looking for the peculiarity. In mouth breathing the lower jaw

FIGURE 2.

usually drops only sufficient for the passage of the same volume of air as would pass through the nasal cavities, which is only about one-half inch. Old people often sleep with the mouth open and frequently to the fullest extent, but these deformities of the jaws and teeth never occur after the eruption of the teeth, say at the twelfth or fifteenth year. When one opens his mouth he is conscious of a tension of the orbicularis oris, but not of a pressure of the buccinator, no matter how wide it may be opened. This muscle being under the control of the will is always passive except in the act of blowing or eating, therefore contraction during sleep is wholly out of the question. As the buccinator muscle extends anteriorly to the first bicuspid only, it can produce no effect upon the V-shaped variety of deformity, in which is also found the contracted vault. Therefore the only deformity that is likely to be produced is the saddle-shaped variety, which is out of the question for reasons which I shall

explain later. The orbicularis oris muscle cannot produce the contraction, because when the mouth is open the pressure exerted on the six anterior teeth is backward. Thus the teeth are carried in the opposite direction from that which must be taken to produce this deformity. Again the pressure is just as great upon the incisors as upon the cuspids, thus holding them in place. More force is exerted by the orbicularis oris upon the six anterior teeth when the mouth is open than can be exerted (if it were possible) by the buccinator muscle, which would tend to hold the anterior teeth in place. For years it has been demonstrated by dentists in regulating teeth that it is very rare for the apices of the roots of teeth to move when pressure is brought to bear upon the crowns of teeth for the purpose of regulating them. This being the case, teeth having long roots like the cuspids are less liable to move than teeth with short roots like the lateral incisors and bicusps. Since in the moving of a tooth the greatest change which takes place is at the neck, it stands to reason that the greatest absorption and deposition of bone takes place at that point. The roots of the cuspid teeth are larger and longer than any other teeth in the jaw; unlike other teeth the germs are situated considerably higher and farther toward the outside of the alveolar process, so that when they come close into position they diverge from the apices to the crowns, while all the other teeth stand nearly or quite perpendicular, thus showing that the roots of these teeth do not influence the hard palate. I have shown that the first permanent molar and the teeth posterior to them are never involved. I have also shown that the centre of the muscle in both directions is located at this tooth. How is it possible, since all the teeth are covered by the muscle upon one side, that half are carried inward and the other half remain normal? Again, if mouth breathing is the cause of the contraction, both sides must contract alike, and the deformity must be uniform upon both sides, which is never the case. Muscles do not contract to a degree sufficient to produce the pressure necessary to produce a deformity. It is inconsistent with our knowledge of the influence exerted by muscular structure in other parts of the body. Some of the muscles of the chest exert much more pressure in respiration than it is possible for the buccinator to do, during sleep, yet no one would expect to find the ribs modified by this process. The pressure of the tissue upon the crown of teeth is not sufficient to affect the alveolar process through the roots of the teeth, but even if it could modify those spongy structures its force would stop there, and would not extend to the osseous vault, bending it out of shape. In most of these cases the superior maxilla and the diameter of the alveolar process and teeth is very much smaller than the inferior max-

illa, alveolar process and teeth; in such cases the muscles and cheek could not reach the teeth and alveolar process upon the upper jaw. This is always the case in the worst forms of irregularities. The changes which take place in bone are not a bending in at one place and forcing out at a weaker point to compensate for the space lost, but are an absorption and deposition of bone at the point of pressure. And even if such were the case the strong pillar of bone situated at the very point of contraction of the alveolar process, together with the nasal septum, both form a strong bulwark for the resistance to the pressure which is situated quite a distance from the top

FIGURE 3.

FIGURE 4.

of the vault. Again, it would be as impossible to produce pressure sufficient to break the dental arch as it would be for the weight of a building to break the arch of a door or window. The tongue exerts a much greater force in the act of swallowing and would prevent the inward movement of the teeth if so slight a pressure as the muscles of the cheeks were the cause of the deformity. For the sake of the argument, let us suppose it were possible for the buccinator muscle to produce this contraction; we should then expect to find the modification of the osseous structures

uniform. This would shut out semi-V (Fig. 3) and semi-saddle-shaped arches (Fig. 4) entirely, and a majority of other irregularities of the teeth in which there is bilateral asymmetry, for however much one would incline to the prevalent theory, no one would dare to assert that the muscle will act on one side of the mouth, while that on the opposite side remains passive. Partial V- (Fig. 5) and partial saddle-shaped arches (Fig. 6) make it still less plausible. In these we meet with sudden bends inward where only one or two teeth may be involved, which could only be produced by a centralization of force on one given point or fibre of muscle, a peculiarity of function that has never yet been ascribed to muscles. The muscle being penniform in shape, it would be impossible for one or two fibres of the muscle to exert its influence upon a bicuspid. It would naturally lap over two or more teeth. Lastly, if the buccinator acts as all muscles uniformly throughout its extent of contraction, below its median line it is just as effi-

dle and partial saddle shaped arches we find the alveolar process built up about the teeth in the precise uniformity to the nature of the shape of the arch. If we take 3,000 models of the upper jaw and arrange them in groups according to the forms here represented and then examine very closely the arrangement of the teeth in each group, we will be unable to find any two alike in either group; thus showing that an external force acting upon the jaws from the outside could not possibly be a cause. If it were possible all the models of one variety would resemble some exact form. Dr. Delavan says that "The prominence of the anterior region of the alveolar arch is still further increased by the projection forward of the superior maxilla at this point, and of the upper teeth." The doctor is quite mistaken as regards the "projection forward of the superior maxilla." The maxillary bone never protrudes in front in this class of cases, it is only the alveolar process which is carried forward by the projecting teeth. The only tissues involved in these

FIGURE 5.

FIGURE 6.

deformities are the teeth on the one hand, and the alveolar process on the other.

cient in producing a narrow contracted arch as in its upper portion, and we should expect to find the lower maxilla contracted whenever the upper one is, which is contrary to facts. A V-shaped arch can never occur upon the lower jaw, if the teeth articulate normally, because these teeth strike inside of the upper, and are thus prevented from moving forward. A saddle, partial saddle and semi-saddle arch may occur on the lower jaw, but these deformities are not often seen. When they do occur they are the result of improper occlusion with the teeth of the upper jaw. We always observe in semi-V and partial V-shaped arches that the alveolar process is contracted upon the side of the deformity. If one side is contracted more than the other we shall observe that the alveolar process is contracted in proportion to the amount of deformity; the vault on that side is not carried up beyond the other side, which is normal. In the saddle, semi-sad-

In most cases the cause of these deformities is arrest of development of the maxillary bone. This condition is due not only to hereditary influence, but also to direct causes, such as the eruptive fevers and all lesions which are constitutional and which produce long sickness. When arrest of development of the superior maxilla takes place we always notice a depression at the *alae nasi* and a sunken condition of the bones of the face on the line drawn from ear to ear, and occasionally extends up to the floor of the orbits. If we will examine closely the faces of an audience in Chicago we shall observe that from forty to fifty per cent. of all these people have this arrest of development of the superior maxilla. Such being the case, arrest of development must necessarily extend to the bones of the nose, thus producing mouth breathing. Ziem has frequently shown that if one nostril of a rabbit be permanently closed and the animal killed after it has attained its full growth, the nasal cavity of

the affected side will be found to be undeveloped and asymmetry of the face will take place. Arrest of development of the bones of the nose, and hypertrophy of the bones and mucous membrane will ensue as a result. A good illustration of hypertrophy of mucous membrane from want of use is observed by dentists when the gums puff up, thicken and extend one-half to three-fourths of the length of the teeth from want of brushing. It would be useless for any one to say that mouth breathing is the cause of one case of V-shaped arch in every twenty, and that some other cause produced the rest of the deformities. We must have a law which will work in all varieties of contracted arches as well as the V-shaped, which variety constitutes a very small percentage of the whole. I have watched the development of these different varieties for the past fourteen years, have taken impressions of the mouths of some of the most marked cases every three months and

compared them. I have also produced most of these forms in the movement of the teeth for the purpose of correcting deformities.

I regret that it will be impossible at this time to show how these different forms of irregularities of the teeth are produced, but they are nicely described and illustrated in my work upon "Irregularities of the Jaws and Teeth and Their Treatment." I will, however, say that they are caused by the long diameter of the dental arch being too great for the long diameter of the superior maxilla. Having then discovered the cause (that of arrest of development of the maxillary bones) of contracted jaws and irregularities of the teeth, have we not a good foundation to work upon to discover the cause of deflected septum and mouth breathing?

The following table will explain the difference in the height of vaults, both in normal and defective jaws:

HEIGHT OF VAULT—NORMAL JAW.

TREATMENT OF HYPERTROPHIED TONSILS BY MEANS OF IGNIPUNCTURE.

Read in the Section on Laryngology and Otology at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY GILBERT I. CULLEN, M.D.,
OF CINCINNATI, O.

Consulting Laryngologist to Cincinnati Free Hospital for Women;
Clinical Demonstrator of Laryngology and Otology in the Cincinnati College of Medicine and Surgery, and Clinical Lecturer of Rhinology and Laryngology, in the Women's Medical College of Cincinnati.

There is probably no disease with which the laryngologist has to deal with more frequently than enlarged or hypertrophied tonsils, and consequently a successful method of their treatment, I trust, will prove of interest to all.

This condition, while not presenting the unfavorable prognosis of many forms of throat disease, yet I think will at times prove quite as distressing and a source of as much discomfort to the patient, as some of the most serious maladies with which we come in contact. As it is not the object of this paper to present the various forms of hypertrophy or disease of the tonsils or their attending symptoms, I will not enter into a consideration of these points except where they bear a direct relation to some of the principles upon which the treatment is based.

The galvano-cautery possesses the power of filling a double vocation, that of completely dissecting the tonsil and that of merely reducing it in size by the cicatrization of the tissue of which it is composed.

Relative to the first function might be mentioned, the able contribution to this subject by Dr. Pyncheon, who, in a paper read before the Chicago Medical Society, October last, clearly described his method of the complete removal of an hypertrophied tonsil by means of a thorough dissection with the galvano-cautery electrode. I would thoroughly endorse this means of complete removal of the gland whenever the indications for such action present themselves. Where it is desirable to employ a galvano-cautery snare, I would recommend the one made by Hazard & Co., of New York, as undoubtedly the safest and most practical instrument that has been devised for this purpose, and should be used where the tonsil is so located as to enable its application and in cases in which excessive hæmorrhage is anticipated.

In the selection of the electrode for puncture, I use one to correspond with the size of the lacunæ, and one that requires some slight pressure to insert it into the crypt. Cocaine is first applied to the tonsil, and a solution of from 4 to 10 per cent. being used, either in combination with phenol as recommended by Gluck, or the pure cocaine, either of which will insure immunity from all pain or discomfort during the procedure. I prefer the addition of phenol to the cocaine solution, as I think the constitutional effects of the latter are less, and the degree of anæsthesia greater.

The electrode should be inserted to the depth of the lacunæ or follicle of the tonsil, and two or three punctures in close proximity should be made at one sitting, to be repeated in from three to six days, as the condition of the gland will warrant. This to be followed by a soothing antiseptic spray of menthol, resorcin, or a modification of the well known Dobell's solution, which formula is somewhat improved by substituting bichloride of mercury in the strength of from 1 to 1,000 to 1 to 4,000 for the carbolic acid, tr. ferri chlor., and glycerine, equal parts; and many others might be mentioned.

Pyncheon makes use of the bicarbonate of sodium in saturated solution, and if the after-inflammation become severe, he uses a mixture composed of tincture of iron and chlorate of potash in glycerine—one dose, containing from 6 to 12 minims of the iron and about 4 grains of the potash, every 2 hours. This treatment I have found to be very satisfactory in a number of cases. In cases of after-hæmorrhage from galvano-cautery puncture, which are *very rare*, I order the patient to take a sip of a mixture composed of tannic acid 2 parts and gallic acid 1 part, with sufficient water added to render it the consistency of a thick cream; this has invariably checked the hæmorrhage at once.

In operating it must be borne in mind that the external carotid artery is about three-fourths of

an inch from the tonsil and the internal carotid about one-half inch; these distances may be materially increased by traction upon the organ, as it has been demonstrated that the cellular tissue between these arteries and the tonsil is elastic and yielding and does not draw the vessels with it when traction is made upon it.

Sajous says that the soft form of hypertrophied tonsils will yield the best results from this method of treatment.

One of the principal advantages of this method of operating is its comparative freedom from danger either from hæmorrhage or septic infection. It is well known that, although exceedingly rare, alarming hæmorrhages from operations upon the tonsils have occurred, cases being reported by Agnew, McCarthy, Velpeau, Delavan, Max Thorner, and others, some of them necessitating the tying of the carotid artery in order to check the bleeding. The advantage of the cautery knife always being surgically clean is also a most important point, as it can readily be appreciated that the electrode, although reeking and loaded with germs, is rendered perfectly aseptic the moment the current is turned on. The process of sterilization being performed by the only perfectly reliable germicide—heat.

The degree of heat used is that of a moderate red, the knife being allowed neither to cool to a black heat before its removal from tissue, as pain and hæmorrhage will result, nor to attain anything like a white heat, as in that case the pain will be more severe and the danger of injuring surrounding tissue greater. Lennox Browne recommends that the knife be used either at black heat or a dull red, and considers anything approaching bright red or white heat as positively dangerous and to be avoided under all circumstances.

I make use of the finer pointed electrodes for the puncture and the flat knives for smoothing off any ragged edges or surfaces that may remain.

After trying all makes of batteries, I think the new Edison-Leland gives promise of proving the most satisfactory, as it requires absolutely no attention until entirely run down, while the process of manipulating it is the same as that of a storage, viz.: simply close the switch on electrode and the current is made, no lowering and raising of elements, and it will run a light steadily for about 8 hours. This battery also serves admirably for the purpose of operating my motor.

The main indications for reduction of tonsils by galvano-cautery might be summarized as follows:

1. When tonsils have ceased to perform their function by reason of interstitial thickening and occlusion of the lacunæ of the glands, in which condition the mouths of the crypts becoming blocked with the accumulation of sebaceous matter, which rapidly decomposes, they form an ex-

cellent culture medium for various pathogenic germs which may ultimately be absorbed into the lymphatic system.

2. That when a tonsil shows itself competent at short intervals to become inflamed and give rise to peritonsillar abscess.

3. Where the tonsil is so situated that it is a matter of great difficulty as well as danger to use the tonsillotomy, and from extensive adhesion of the pillars, likely to cause severe hæmorrhage by their being cut.

4. In all cases where the patient is of a hæmorrhagic diathesis or in other cases in which alarming hæmorrhage is feared.

5. Where patients will not consent to the use of the knife and yet the demand for the removal of the gland is imperative.

NOTES ON ARISTOL IN THE TREATMENT OF THE DISEASES OF THE NOSE AND THROAT.

Read in the Section of Laryngology and Otology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 6, 1891.

BY WENDELL C. PHILLIPS, M.D.,

ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, THROAT DEPARTMENT, NEW YORK.

Nearly every month a new antiseptic is presented to the medical profession, each claiming to outdo all its predecessors and to be perfect in all its attainments.

But experiments have proved most of them to have one or more obnoxious qualities that greatly interfere with their usefulness in the sphere for which they have been recommended.

One, if used in sufficient strength to become a true antiseptic, is found to be a local irritant.

Another corrodes the instruments and unless great care is used will poison both the patient and the operator.

A third is accompanied by an odor so pungent and disagreeable that few patients will submit to it, and the usefulness of still another is greatly lessened by the staining to hands and clothing that results from its use.

All of the earlier antiseptics were handicapped by their poisonous qualities, and consequently could only be used to a limited extent.

Aristol, one of the more recent ones, possesses some qualities that have attracted the attention of various observers, and a combination of the drug has been suggested by the writer that is bringing about good results both in nasal and in general surgery, and which will be described in a later part of this paper.

Aristol is a combination of iodine and thymol, and is known as an iodide of thymol.

It was first suggested by Drs. Messinger and Vortman, of Aix-la-Chapelle, as a substitute for iodoform.

It is described as a "fine yellowish red powder which is inodorous and nontoxic."

It is insoluble in glycerine and very sparingly in alcohol, but very soluble in ether, chloroform, and fatty oils.

It is decomposed by heat and by light, and after decomposition its odor is similar to that of iodoform. Reports of its use, in the treatment of diseases of the skin, ear and mucous membranes of the nose, throat, and vagina, have come from various sources and the consensus of opinion is that it is nontoxic, and that its antiseptic properties are equal to, and in some cases superior to iodoform.

Lowenstein¹ used it in three cases of simple ozæna by insufflation and says "after a few days the fetor had disappeared, the formation of crusts was reduced and the headache ceased".

He has also used it in solution with ether in the proportion of a dram to the ounce with good results.

Hughes² also used it by insufflation in nine cases of rhino-pharyngitis, accompanied by ozæna, and reports great relief in all the cases; the fetor was greatly reduced, and the crusts were easily removed. He believes it to have the power to stimulate the secretion of mucous membranes.

Rhorer³ reports twenty cases of acute catarrhal otitis media, treated with insufflations of aristol in powder and notes that the secretion is quickly reduced in quantity; the mucous membrane of the middle ear becomes smooth, and the swelling disappears in a few days; the perforation heals if there was no great loss of substance.

Brocq⁴ reports a case of large ulcerating superficial epithelioma of the face rapidly cicatrized by the use of aristol, and believes it to possess the power of causing rapid cicatrization superior to anything that has heretofore been used in similar cases, but does not consider it a specific for the disease. He further remarks "that the most remarkable evidence of the cicatricial power of aristol is observed in superficial ulcerations of a tuberculous origin."

Thus in a case of elephantiasis of the foot the ulcerations, which had been treated for a long time with lactic acid, camphor, naphthol, and iodoform, respectively, were cicatrized within a fortnight by the application of powdered aristol.

Another tuberculous ulcer developing on an old scrofulo-tuberculous cicatrix, has been healed in twelve days.

It has also been used by Gaudin, Seifert, Erchhoff, Schirren, and Neisser in various skin affections.

The method of using it has been chiefly in

¹ Int. Klin. Rundschau, May, 1890.

³ Archives internationales de Laryngologie, 1890, No. 2.

⁴ Bull. and mem. de la société, médicale des Hôpitaux de Paris, May 1, 1890.

powder, but in some instances it has been made into ointment, in varying proportions and, when a solution was required, in ether, chloroform or flexible collodion.

My experience with the drug dates from August 1890. I first used it at the Manhattan Eye and Ear Hospital in solution with flexible collodion in the proportion of a dram to the ounce.

Several cases of chronic atrophic rhinitis with ozæna, one case of syphilitic ulceration of the septum, and one case of simple ulceration of the septum were treated with this solution by means of a cotton probe.

In the cases of ulceration of the septum the results were good, and healing was accomplished in both.

In the case of ozæna (and I speak of ozæna as a symptom, not as a disease) the results were not so satisfactory but were sufficiently good to warrant a further use of the drug. The odor was very much lessened after a few days treatment and the secretion became less inspissated.

These comparatively favorable results led to the conclusion that if aristol could be brought more thoroughly into contact with the entire surface of the diseased membranes, far more could be accomplished both in correcting the disagreeable odor and perhaps destroying the cause of it by bringing the membrane into a healthier condition.

To bring this about, no matter what remedy is to be used it stands to reason that it must be brought into contact with the entire diseased surface, and as a rule, a very large surface of the nasal tract is in a diseased condition in cases of chronic atrophic rhinitis.

The anatomy of the nasal cavities with their various projections, depressions, processes and fossæ, is such that a thorough application cannot be made by a cotton probe.

Treatment by insufflations as recommended by several of the gentlemen previously mentioned is preferable, and I have resorted to it in several cases, but found it difficult to make a thorough application without using a large quantity of the drug, much of which would be wasted, and its expense will not allow of waste.

It has become an axiom in the treatment of nasal diseases that, of all the methods resorted to for local medication, none are to be compared either for convenience, thoroughness, or effectiveness, with the spray.

Believing this to be true and believing also that, if aristol could be used in the nasal cavities by means of a spray, much more could be accomplished in the treatment of the cases under consideration, I endeavored to get a solution of the drug that could be used for spraying and would at the same time remain permanent.

Knowing that the liquid petroleum products have deservedly largely taken the place of aque-

ous solutions for spraying purposes; and knowing also that the same principles that obtain when menthol, eucalyptol, etc., are used in solution with liquid petroleum would hold good with aristol, I succeeded in having a solution made that is applicable for spraying purposes.

Aristol is not soluble in any form of liquid petroleum, but with care a solution can be made by first dissolving the aristol in a small quantity of pure almond oil, afterwards adding the liquid petroleum.

A solution of thirty to forty grains to the ounce answers for all nasal requirements. It is well to flavor with a little oil of wintergreen.

I have treated twenty-two cases of ozæna with the spray as above described. Twenty of these are the ordinary type of this condition, one is due to inherited syphilis with an obstruction due to a deflected bony septum, and with a partial adhesion of the soft palate to the posterior wall of the pharynx, and the other case is supposed to have a piece of zinc plate imbedded in some portion of the nasal tract which I have been unable to find. In this case the odor was so fetid that the patient could detect it herself.

In fact, all of these cases are of a severe type, and presented large collections of inspissated crusts. At the first visit the crusts were removed before using the aristol spray, but afterwards little was done except to use the spray.

The patients are taught how to use the spray properly at home and are directed to use it night and morning. Much depends upon the way it is used, and patients should be instructed to inhale the spray.

The results so far obtained have been similar in all the cases.

The odor of the breath in every case has entirely disappeared in from two to five days, and has not returned, but the cases are still using the remedy. Consequently it is impossible to state how permanent this result is. However, if the ozæna can be held in check only by the daily use of aristol, more is accomplished than ever has been done before.

The formation of crusts, has, also, been greatly lessened in every case; a fact that is probably due to the stimulation of secretion caused by this drug.

It is certainly true that aristol excites a copious secretion from all mucous membranes, but the secretion is less noticeable from the nasal than from other membranes, notably the urethra.

This power to induce a more copious, and therefore a healthier secretion lessens the formation of crusts, and by so doing it also lessens the odor which comes from the decomposition of the secretion.

This result tends to a healthier condition of the membranes because the secretions do not remain in contact with them until they decompose.

I venture to predict that if aristol proves to be possessed of actual curative properties in catarhal diseases the results will come from its power to stimulate secretion as well as from its disinfectant properties. That it is a useful agent cannot be denied, but conclusive judgment cannot be passed until it has been given a longer trial.

PHYSICAL CULTURE A NECESSITY.

*Introductory Lecture delivered at Rush Medical College, Chicago,
Sept. 29, 1891.*

BY JOHN B. HAMILTON, M.D., LL.D.,

Gentlemen:—I am deputed by my colleagues to bid you welcome to these halls, and to this oldest medical school of the Northwest.

It ushers in its forty-ninth annual course, with every prospect that the new requirements of advanced general scholarship, as preliminary to admission, are being well met, and that a solid advance has been made in the attainments of the medical students of this metropolis.

We welcome you, then, as more nearly *frater* than *discipulus*, and it will be understood that the educational seed sown hereafter will fall upon soil well prepared, and coming as you do from different environment, and perhaps to a more artificial life, I do not know that I can on this occasion render you a better service than to direct your attention to the necessity of caring for your body not less than for your minds. The mental digestion of a student corresponds very closely to the physiological digestion, and many a man has failed to become a learned man from physical disability alone.

You may occasionally read of a soured misanthropic dyspeptic like Carlyle; whose mental activity is very great; but such a person is an exception, a veritable *lusus nature*. The rule is that the better care taken of the body the more perfect the mental processes. Dyspeptics are usually made not born such.

As preliminary, then, to the study of the practice of the art, I will for this evening's lecture take up the subject of

PHYSICAL CULTURE, ANCIENT AND MODERN.

Within a few years there has been much said in America on the subject of physical education. It had begun to be apparent that, with all our boasted progress in wisdom, in general intelligence, and in the arts and sciences, we had omitted from our curriculum any study having for its object the systematic training of the body.

The body cannot become a perfectly working machine without culture or training, any more than the mind can become intellectually expert without that drill which we call education. We do not look for able logicians in those who have not had mental exercise. We ought not to ex-

pect sound bodies in persons whose every free and natural movement has been repressed in childhood, cramped by fashion, and neglected throughout life.

It is not a pessimistic view of the case to consider that one-fourth of our population of military age probably could not pass a physical examination as recruits. It is probably within bounds to say that a majority of persons thus disqualified have become so from neglect of muscular exercise. The hollow-chested consumptive was not long since the type of the scholar, and the moral of this lesson was to teach people to avoid schools, for fear of the production of physical deformity or imbecility. It was this feeling that college graduates were unfitted to deal with the rough elements of daily life in the world, that brought about the changed sentiment whereby our colleges now encourage manly sports and exercises. Like all reforms, when once instituted it may go too far, yet with all our knowledge on the subject, few private or public primary schools devote any appreciable time to the cultivation of sound bodies. This is left to chance. What would become of the mind similarly neglected? Are we prepared to admit that the mind is inferior to the body? We cultivate and stimulate one, and mortify and neglect the other. The brain cannot live without the spinal cord and sympathetic ganglia, and healthy, active circulation is necessary to cause clear, vigorous, mental actions. Is it not then of first consequence that our primary education should begin with training the muscles, the nerves, the eye, the ear and the hand at the same time we commence to stimulate the brain by precept.

"Ut sit mens sana in corpore sano." "Let me have a sound mind in a healthy body," says Juvenal, in his prayer to the gods, and there is but little doubt that the ancients thoroughly understood the philosophy of the case; but it was "professionalism" that ruined the Grecian gymnasium and transformed the manly athlete into a commercial harlequin, or a repulsive brute.

The physical welfare of the people has been one of the chief cares of states since the organization of governments among men. First for physical self defence, and second for conquest, and it has been found that where the highest types of men existed, there also were found examples of the highest type of the human intellect. The poetry of Homer grew on the same soil that produced Leonidas and his hardy veterans, and viewing Greece as a whole, without reference to the internecine wars and minor differences which separated it in states, we may truthfully affirm that the same civilization that produced the Spartan may justly display at Athens the art of Praxiteles and Phidias, the eloquence of Demosthenes, the wisdom of Socrates, the jurisprudence of

Solon and Spartan Lycurgus, the logic of Aristotle, the learning of Plato and Euclid, the incomparable skill of Hippocrates, the histrionic art of Æschylus and Euripides, and the histories of Xenophon and Herodotus. What would Greek sculpture have been, had it not been for the athletic exercises that gave form and symmetry to the human figure in the times contemporary with the productions of the immortal statuary? If the muscles of the Homeric heroes were nudely prominent, was it not gigantic intellect that recorded their prowess? Was it not phenomenal skill that chiseled their likenesses in enduring marble?

The Roman warriors were also contemporary with her orators, although the art of the period was wholly Greek.

With luxury and idleness came physical and mental decay.

Loss of physical strength was accompanied by general depravity. When Lycurgus forbade the art of writing in Sparta he at the same time did not neglect to stimulate the mind by requiring the laws to be memorized and transmitted by the mouth, and although in our times such rigorous rules as those by which the Spartans were governed would be unendurable and unnecessary, it is evident that they were adapted to their times, and that they succeeded not only in developing the ancient Doric character, but in gaining Lacedæmonian ascendancy. The Spartans indeed valued the sound body to the most extreme degree. No other Grecian state ever found it necessary to destroy the deformed children. The Spartan custom required that the new-born child should be carried to certain examiners who held court (*Lesche*) λεσχῆ, where the infants were carefully viewed; the well-formed and strong were ordered to be cared for, the puny or delicate or misshaped ones were condemned and "cast into a deep cavern in the earth near the mountain Taygetus, as thinking it neither for the good of the children themselves, nor for the public interest that they should be brought up, since nature had both denied them the means of happiness in their own person, and of not being serviceable to the public, by not enduing them with a sufficient measure of health and strength." (Potter, *Grecian Antiquities*.)

While the Greeks in general were not inclined to follow the Spartan custom of destruction, yet the children of the poor were "exposed," and it may well be believed that it cost a less pang to expose a deformed than a healthy infant. When the child was to be educated, the whole scheme was comprised in four parts, grammar, music, gymnastics and the art of drawing and painting. Gymnastics, however, were considered of transcendent importance, and this part of the period of education occupied as much time as all the other branches. The legislation of Solon was

particular in regard to the gymnasia, and there was a superintendent called a *gymnasiarch* who was a civil magistrate, having jurisdiction over the gymnasium, and all who frequented it. This *gymnasiarch* had power to remove any teacher or philosopher, in his discretion, when he found any such person having an injurious effect on the youths. Under the direction of the teacher (*gymnastes*) such kind of gymnastic exercise was selected as seemed best suited to his peculiar constitution. Galen has mentioned these teachers and it appears they were informed as to the physiological effects of exercise upon the body in general, and the best means of correcting physical defects, whether of malformation or development.

Sprengel refers to this topic as follows:

1. "The games of the Greeks had an immediate influence on the art of war, because gymnastics were cultivated for the conservation of health, and as well by the physician to cure diseases. It is for this reason that the gymnasia were consecrated to Apollo, the god of the physicians, and many of the persons employed were of their order. The *Alliptes* bore the name of physicians, and they treated by this means the lighter ailments."

Herodotus, a pupil of Agathinus, who practiced medicine at Rome in the reign of Trajan, and who was zealous in the pneumatic sect, recommended all the gymnastic exercises, especially horseback riding, in acute diseases, oil baths, swimming in the sea, and mineral waters.

The learned Oribasius, who flourished in the fourth century, who was one of the most elegant of the ancient medical compilers, had very clear ideas on the importance of physical education of children—ideas which are well worthy of attention to-day. He thought the physical education should always precede the mental education.

The famous surgeon, Antyllus, recommended singing as an exercise to develop chest capacity in pulmonary diseases; and in later times the surgeons may fairly claim the credit of bringing gymnastics once more prominently to the front as a remedial measure, and, as a sequence, its modern revival. Ambroise Paré, the great French surgeon, who flourished in the sixteenth century, again proposed massage as a revulsive in cases of wounds of the head, and Sabbatier, in 1772, published an interesting work on ancient gymnastics. No surgeon has surpassed Sabbatier in learning, nor did any in his time surpass him in practical handicraft.

Tissot, of Switzerland, in 1780 published a work entitled "Medical and Surgical Gymnastics."¹

But it is not intended to include a study of medical gymnastics as within the scope of this

¹ *Gymnastique Medicinale et Chirurgicale.*

lecture. Suffice it to say, that as a therapeutic resource it has well-defined uses, and we see in the modern *masseur* the enthusiast in this branch. Those interested will be amused and instructed by a glance at Moritz Schreber's little volume, published in London, Edinburgh and Leipsic in 1856. Instructed by some of the measures proposed, and amused at others, such, for instance, as the radical cure of hernia by muscular movements. As for the *masseur* himself, has he not invaded the entire medical territory? With his "Swedish movement," and his mechanical "system," his weights and pulleys, and his little hammer and tongs, he is certainly much abroad in the land. (Pardon this digression—this "excursus," as good old Becker puts it in Charicles and Gallus.)

Let us return to the Greek gymnasia. The same general system was pursued throughout Greece, but whereas in Sparta the gymnastic exercises were looked upon as a necessary basis for the military training and the hardships of the field, in Athens the higher, broader view was taken, that the gymnastic exercises were necessary not only to make expert and hardy soldiers, but as giving strength, beauty and health to the human body, and making it nearer the divine image.

It may be interesting to give a part of Vitruvius' account of the construction of the Greek gymnasium.

I follow Gwilt's translation :

Of the *Palæstra* (indoor gymnasium) :

Though not used by the people of Italy, it seems proper that I should explain the form of the *palæstra*, and describe the mode in which it was constructed by the Greeks. The square or oblong peristylia of *palæstra* have a wall around them which the Greeks call "*δίανυλος*," two stadia in circuit. Three of the sides are single porticos; the fourth, which is that on the south side, is to be double, so that when showers fall in windy weather, the drops may not drive into the inner part of it. In the three porticos are large recesses (*exedrae*) with seats therein, whereon the philosophers, rhetoricians and others who delight in study may sit and dispute. In the double portico the following provision is to be made: the *ephebum* is to be in the middle, which is in truth nothing more than a large *exedra* with seats, and longer by one third than its width. On the right, in the *coriceum*, immediately adjoining which is the *conisterium*, near which, in the angle of the portico, is the cold bath, which the Greeks call *λουτρόν* (*loutron*)."

He then gives technical explanation of the location and construction of the *frigidarium* (cold room) and the *sudatorium* (sweating room) and the hot bath, and continues speaking of porticos, which are to be "so formed that as well on the side next the wall as on that where the columns stand, there are margins for paths of not less than ten feet; the center part is sunk one foot and a half from the path, to which there is an ascent of two steps; the sunken part is not to be less than twelve feet in width. Thus those

who in their clothing walk around the paths will not be incommoded by the annointed wrestlers who are practicing."

The learned Becker thus takes his imaginary Charicles to a gymnasium :

He found the gymnasium very full of company. In the arcades surrounding the peristyle were groups of men, young and old, engaged in discourse of various kinds. Here a sophist, seated amidst his scholars, was discussing by the method of interrogation the pros and cons of some doctrine of ethics. The large semi-circular bench of marble on which he sat could only accommodate half his auditory, so the others stood in front to catch the wisdom that proceeded from his mouth. Here a rhetorician was making a critical examination of a speech elaborated by one of his pupils. In several places little knots had formed, and were talking of the important occurrences in Asia. News had just arrived from the Macedonian host, announcing the continuance of the siege of Tyre, and some assayed a display of their topographical acquirements by drawing in the sand with their sticks a plan of the city and its position. In the great court many were engaged in all kinds of exercises, while others were already hurrying to warm or cold baths, or annointing their limbs with pure oil in the *Elæothesion*.

Charicles strode through the *Palæstra* to the exercise grounds in the open air. Here were several running races, amid loud acclamations of the beholders, who encouraged first one, then another; others stood ready to jump, with the leaping weights in their hands.

And then Charicles, with his friend Ctesiphon, engaged in a wrestling match, and then went to the bath. Charicles' father, we are told, "was averse to the one-sided exertions of the *athletæ*, yet a sensible course of gymnastics, as well as chariot driving, and the chase, together with the intercourse of learned men, ranked with him as the only occupation befitting a free-born youth."

The Greeks, however, found that the ordinary training in the *gymnasia* was not sufficient to enable the pupil to win prizes at the festivals where the great national games were celebrated, and a severer course of training was instituted in the *palæstra* for certain of those who gave their lives to their calling.

They were called *athletæ* (athletes), and they were the first professionals, for their whole business was to win the prizes at the Isthmian, Nemean, Olympian and Pythian games. Great was the attention bestowed upon the *athletæ*. The *gymnasiarch* superintended their exercises in person, and their diet was carefully regulated by the *Aliptes*. The fact that the "*agonistes*," or amateurs, could never win as against the professional *athletæ* gradually resulted in the overthrow of the whole system. The importation of the *athletæ* to Rome took place in B.C. 186, and they gradually acquired greater and greater privileges. Professionalism, now rightly considered as an obstruction in the path of true physical education, is therefore of very ancient lineage. It is not surprising that when the professionals had absorbed all the honors of the game, we find that the pendulum of public opinion swung away

from enforced exercise, and away from the gymnasia.

THE MIDDLE AGES.

In the mediæval times the golden days of the Grecian Gymnasium seemed past beyond recall, for the age was essentially military, and learning was relegated to the cloister. Travel and the tourney were the essentials. The well-known passage in the "Two Gentlemen of Verona," wherein Panthino discourses of Proteus' education, gives the view taken of the matter:

"He wondered that your lordship would suffer him to spend his youth at home,
While other men of slender reputation, put forth their sons to seek preferment out.
Some to the wars to try their fortune there;
Some to discover islands far away; some to the studious Universities.
For any or all these exercises, he said that Proteus your son was meet,
And did request me to importune you to let him spend his time no more at home,
Which would be great impeachment to his age, in having known no travel in his youth."

Thus Antonio:

"Nor needst thou much importune me to that
Whereon this month I have been hammering.
I have considered well his loss of time,
And how he cannot be a perfect man,
Not being tried and tutored in the world.
Experience is by industry achieved,
And perfected by the swift course of time.
Then tell me, whither had I best send him?"

Panthino then informs Antonio that the Emperor is at court, and says:

"'Twere good, I think, your lordship sent him thither.
There shall he practice tilts and tournaments,
Hear sweet discourse, converse with noblemen,
And be in eye of every exercise,
Worthy his youth and nobleness of birth."

When Hamlet wished his mother, the Queen, and his uncle, to conclude that he was really insane, he could think of no surer way to impress that conclusion upon them, than by telling Guildenstern that he had "lost his mirth," and "had foregone all custom of exercise" — and King John spoke in hypocritical commiseration of Prince Arthur's lack, while in prison, of the "rich advantage of good exercise."

"There are," says Hallam, "three powerful spirits which have from time to time moved over the face of the waters, and given a predominant impulse to the moral sentiments and energies of mankind. These are the spirits of liberty, religion, and of honor. It was the principal business of chivalry to animate and cherish the last of these three, and whatever high, magnanimous energy the love of liberty or religious zeal has ever imparted, was equaled by the exquisite sense of honor which this institution preserved."

The education of the mediæval knights commenced at the age of 7 years. They were brought up in the castle, and there learned discipline and

the use of arms. Up to the age of 14 they were pages, and accompanied the superior lord in that capacity. At the age of 14 they bore the title of esquire, and then began in earnest the systematic exercises in horsemanship, and feats of strength and activity. According to Joinville, the youths "thus placed in the centre of all that could awaken their imagination, the creed of chivalrous gallantry, superstition, or honor must have made indelible impressions. Panting for the glory which neither their strength nor the established rules permitted them to anticipate, the young scions of chivalry attended their masters to the tournament, and even to the battle, and riveted, with a sigh, the armor they were forbidden to wear." (Hallam.) The state of learning had gradually declined in Europe from about the sixth century. Tournaments were instituted about the middle of the eleventh century, and we find that their original purpose was to encourage the development of high physical courage and activity. The tournament was the legitimate successor of the Grecian games, and gradually became celebrated with every degree of splendor. The ruler of the realm, whoever he might be, not seldom acted as the master of ceremonies, and often participated in the struggle. The victor was crowned amidst the plaudits of the assemblage, he received the prize at the hands of his lady, while the triumphant notes of the minstrels filled the air. Around him were gathered his companions in arms, with nodding plumes and glittering armor, grooms with gaily caparisoned horses, and men-at-arms with waving banners. No scene so soul-inspiring, no tableau more impressive. Is it any wonder that the age of chivalry lasted so long?

With the revival of learning, there was poured upon the knights a fervent flood of ridicule, doubtless on account of the exclusive privileges of the class, not less than on account of their general ignorance. No one has ever charged the mediæval knights with having a superabundance of learning—Charlemagne himself learned to write late in life—and when knighthood lent itself to vagrancy under the name of "knight-errantry," enfeebled by the general changes going on in European warfare, it finally fell an easy victim to the pen of Cervantes.

MODERN PHYSICAL TRAINING.

At the beginning of this century, efforts were more or less successfully made, in various countries, to introduce gymnastic exercises into the primary schools and into the family. Among those active in this work was the famous Swedish *savant*, Ling. Ling considered man as a dual being, where the soul and the body were mutually reactive according to the diversity of their nature, and he sought to harmonize human existence according to this duality. He conceived a

system of physiological exercise which exercised both mind and body, and to this general theory of Ling may be traced the so-called Swedish system, which has been so popular and useful.

In France, and indeed in Europe throughout, gymnastics have been well taught in the military schools, but only recently systematic instruction for civilians has been advocated.

Physical training in England has never died out since the age of chivalry, but on the Continent, at the end of the last century, it had reached a low estate, particularly in Germany, where there was a marked physical degeneration of the people; a degeneration as marked as in America to-day. Napoleon practically ruled Europe, and back of the German Turners' organization was the firm determination to secure a regenerated country. The theories of Father Jahn were preceded by Montaigne and Rousseau in France, Campe, Salzmann, Basedow and Guts Muths in Germany, Pestalozzi in Italy, and Fellenberg of Prussia; but the Germans only seem to have given practical direction to their faith. Fellenberg added military drill to instruction in gymnastics and handicrafts. (Hartwell.) Guts Muths was a pupil of Salzmann at Schaepkenthal, near Gotha, where he had a small gymnasium; the gymnasium was based on the Greek model. Guts Muths became an instructor there, and taught until his death in 1839. Guts Muths wrote the Prussian Minister, Massow, urging the introduction of physical education into the schools, as the best means of reviving the military spirit of the people, but the war soon coming on again, the matter was suspended.

Frederick Ludwig Jahn was born August 11, 1778, and the present high development of physical education in Germany is due to "Father" Jahn. Indeed, it is questionable if the present revival of interest in America is not principally due to the establishment of the American turn societies. Father Jahn's idea was founded in the purest patriotism, and his book on German Nationalism, in 1810, was speedily followed by the founding of the "German Confederacy" in Berlin, November 14, 1810. It was a great undertaking to make a union of the German States, and at the same time to work out the problem of the physical regeneration of the people. Under his active efforts, "turnplaces" soon became the fashion throughout Germany, and in a few years every city of importance had its turnplace. In 1816, turn-schools for girls were permitted in Prussia, and Jahn published his work, the "German Turn Art." But the turners were growing too strong, and as courage is the expression of conscious strength, some of the turners were too bold in their political sentiments, and in consequence, an official war was declared against them, and in 1818 the turnplaces in Breslau and Liegnitz were closed, and in July, 1819, Jahn himself

was arrested as a "demagogue" and brought to Spandau. The turnplaces were for a short time placed under police inspection, but on the 2d of January, 1820, turning was forbidden throughout Prussia. In May of that year, Father Jahn was released from rigorous confinement, but was restricted to the limits of the fortress of Collberg. Jahn's friends were powerful enough to finally secure him a trial, and on December 12, 1825, he was acquitted by the Supreme Court, at Frankfurt-on-the-Oder, but the ministry still pursued him. He was put under bonds, and was forbidden to settle in Berlin or within ten miles of its limits. October 14, 1833, Bavaria had many turnplaces, and a ministerial order announced that "Turn-verein have been established, songs of liberty are being sung; this is very dangerous. Teachers beware." In 1837, turning was again allowed in the Prussian gymnasiums, and in 1840 Jahn was unconditionally released, and just before Christmas he received from King Frederick IV the Order of the Iron Cross of the second class. The turn schools grew and grew, until so well established in popular favor that, by a ministerial decree of January 7, 1844, obligatory turning was introduced into the common schools of Prussia. Two years later, turn schools for females were ordered to be established. The skies seemed bright for the followers of Jahn, but there was the "little cloud no larger than a man's hand" in the horizon. The Frankfurt turn verein was closed by order of January 4, 1848, as alleged, on account of its tendency towards republicanism, and the ministry, with evident purpose of controlling the turners, erected a central school for Turn teachers, at Berlin. But there had already been conflicts of the Kiel students, near Bau, and in Hanau, the German social democratic turn-bund had been founded on the second turnday of the first turn assembly. But the precipitation of the Revolution of 1848 resulted in the exile of many of the leading turners, their emigration to America, and the foundation of turn societies in Cincinnati and New York in the same year. In 1849, the Philadelphia Turn Society was founded, and the societies at St. Louis, Boston, Louisville and Williamsburgh. Later in the year, the American Turner-bund was founded—the avowed object of the "bund" or confederacy being not only the promotion of corporal exercises known as turning, but the promotion of liberty, the welfare and education of all classes, and the extension of turners' societies. That this first turner-bund sympathized heart and soul with the Prussian revolutionists is evident from the fact, that the German women of Cincinnati made a black, red and yellow banner, to be given to the first German State that would be declared a Republic, but the banner was finally committed to the custody of the Cincinnati turn society. October 25,

1852, the "turn father," Frederick Ludwig Jahn, died, at the advanced age of 74, having lived to see the great advance in gymnastic exercises, and having a clear perception of the coming glories of his Fatherland.

With the exception of the "Know Nothing" excitement, the course of turning has run smoothly in the United States, and at this time there are more than 30,000 turners in the United States, and about 260 turn societies. Their watchword is still liberty and education for all, and although we wish they would use English as their official language, I am convinced that their influence is always for the welfare of our common country. In our civil war, the German turners stood solidly for the Union flag, and their valor was attested on many a well fought field. On January 1, 1861, the St. Louis Turners resolved to found a military organization "for the protection of union and liberty," and a week later the Washington Turners organized a shooter's section to help defend the Capital against the secessionists, and the St. Louis, Cincinnati and New York Turn societies were nearly all sworn in the United States service on the first call for troops.² We who reap the benefits of the patriotic ardor of 1861, should not give scanty praise to these stalwart men—they deserve our warmest thanks and commendation. Their courage and valor is well shown by the New York Turner regiment, which marched out of that city in 1861, fully 1,200 strong, and when it returned there were only 460 left; more than half the number were killed in battle, perished as prisoners of war, or victims of the deadly malarial emanations from the Southern swamps. The historic volley fired by the Ninth Ohio (turner's) regiment, at Mill Springs, Ky., January 20, 1862, inaugurated the first victory of our western armies, and laid the foundation of the fame of General George H. Thomas.

But while turning affords our fellow-citizens of German nativity healthful amusement, and inspires them with principles of liberty and patriotism, it is by means of similar organizations, that the native element must keep its place, and perform its duty. It is at this time a patriotic duty to form gymnastic schools and athletic clubs, and by all means at our command stay the tide of physical degeneration that is destroying American manhood and womanhood.

The great colleges are doing their utmost; gymnasia are being equipped everywhere, and youths leaving college may now find in nearly every city a well furnished athletic club.

I fully agree with a recent editorial in *Outing*, to the effect that our modern athletic club houses combine all that is best in the Greek gymnasium with the more luxurious fashions of the Romans,

and that, owing to the exigencies of our climate, we must have houses. The Greek simplicity of costume is neither adapted to our fierce summer heat, with sudden changes of temperature, nor to the winter blasts, that come from our north-western prairies.

Much might be done by hardening from constant exposure, as all history tells us.

When a certain king waged war on the Scythians in midwinter, he found members of their hardy warriors almost naked.

"How can you withstand this bitter cold without clothing?" asked the king of a captive.

"Why do you not cover your face?" replied the Scythian.

"My face is not accustomed to be covered; the skin is hardened," good-humoredly answered the king.

"Sire, we are all face," said the Scythian.

The hardening process we may then admit as possible, but is the game worth the candle? The æsthetic fever is upon us, and let us stick to our houses, and build them as fine as we conveniently can. Let us extract all the dulcet liquid from the orange while it is still juicy, and have some pleasure in life while growing in strength and brawn.

But what are we doing for the young children? A few western cities, under the directly stimulating examples of the turners and the athletic clubs, have begun to establish gymnasia in connection with the regular instruction of the school, and paid teachers of gymnastics have begun to be employed, notably at Chicago and Kansas City; but the melancholy fact remains that the majority of our primary schools are absolutely without any provision for the most elementary physical training. The primary school should be the place where the body is made to grow straight, where all the muscles are exercised properly, and where the young, tender brain is nourished by blood made healthy through active circulation. The colleges are doing good work with the youths and young women, and the clubs and turn societies maintain and keep up the physical standard thus acquired, but the college instructors should have youths sent them with some sort of preliminary physical training. At the preparatory school he begins his classics, his mathematics and physics. Why should he not also begin his physical training at the preparatory? Not only would the results be more perfect when thus commenced, but when we remember that the majority of our youth do not enter college at all, we then realize that unless the primary school be made the place of beginning, the work is never commenced.

When one sees the sickly, stoop-shouldered, knock-kneed, feeble children attempting to become educated men and women, there is no longer reason to wonder at the marvellous in-

² Among the German Turners' regiments may be mentioned the Ninth Ohio, Thirty-second Indiana, Twenty-fourth Illinois (Hecker's), and the First, Second, Third and Fourth Missouri. Milwaukee also sent a turn regiment.

crease of our insane. Every State in our Union has to annually increase the accommodations for the insane, and if this necessity were confined to those States where the population increased with equal pace, it could be accounted for; but we see those States in which there is no increase of population year after year adding to the insane class. This is largely the result of physical degeneration, as shown in flabby muscles, disinclination to exercise, and unhealthy blood. We want no *class* improvement, but we want universal attention to physical training from childhood to adult life; and until the State governments take up the matter as a patriotic duty, we must encourage private gymnasia.

The physical retrograde condition of our native stock cannot be corrected by encouragement of professional athletes. It is well to have a Sullivan to show what may be done by one-sided cultivation, as a specimen of magnificent muscle; a Winship to teach us the physical fact that a man's lifting power can be increased to an almost incredible degree; but these are not the kind of specimens after which to fashion a race. Let us have the highest types of beauty, deftness and strength, combined with mental vigor and chivalrous virtue. Let us have women like her of whom the poet said, "Grace was in all her steps, heaven in her eye; in every gesture dignity and love." And let us have strong men. Let the medical students of this college set the example. Your strong, healthy, vigorous man is never irritable, never "nervous;" he is generous, and he sleeps at night. He is worth something to his country and to all mankind. He exercises his muscles, the blood flows freely in his veins, he is hungry, he digests his food, his brain is nourished, and his mental faculties are active. He lives, and the world is better because he lives. I love to look at a bright, happy-faced man, who takes a full breath and expands his chest; who looks at the rising sun without blinking, and whose face glows with the animation lent it by a pure soul, unvexed by an irritable body. Think what glorious soldiers a regiment of such men would make! How the arts and sciences would flourish under the general stimulus of strong America! Our beloved country would indeed become blessed. Our new America, strengthened by exercise, made happy by good health, might easily outshine the glories of the golden age of Greece, and, "like precious stone set in silver sea," flash its beauty to the sun.

DR. FREIDRICH SCHANTA, of the University of Prague, succeeds Prof. Carl Braun in the chair of Midwifery in Vienna. He is the author of a manual of operative midwifery and numerous lesser works.

SOCIETY PROCEEDINGS.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

The Second Triennial Meeting of the Congress of American Physicians and Surgeons held in Washington, September 22, 23, 24, and 25, 1891.

General Session.

TUESDAY—FIRST DAY.

The Congress was called to order by the chairman of the Executive Committee, DR. WILLIAM PEPPER, who introduced the president, DR. S. WIER MITCHELL, of Philadelphia.

The first scientific matter brought before the session was the discussion on

CONDITIONS UNDERLYING THE INFECTION OF WOUNDS,

Including a Discussion of Disinfection with Reference to Treatment of Wounds, of the Relation of Bacteria to Suppuration, of the Resistance of Tissues to the Multiplication of Bacteria, and of the Effects of Antiseptic Agents on Wounds.

The discussion was opened by

DR. WILLIAM H. WELCH, Baltimore, Md. That the presence of certain kind of bacteria is an essential condition of wound infection is so well established that discussion of this point is not likely to arise. The comparatively simple conception that a wound to which bacteria gain access, necessarily becomes infected, has been greatly modified. The traumatic infection present their own peculiar problem. The doctrine of wound infection involves the consideration of many varying and often complicated factors relating both to the agents of infection and to the individual exposed to the infection.

The subject was considered under the following heads:

1. What are the microorganisms concerned in the infection of wounds, and how do they act?
2. How are we to explain the great differences in the effects produced by the pyogenic micrococci; their apparent harmlessness under some conditions, their fatal influence in others.
3. What are the ways by which bacteria gain access to the wound?
4. How often are bacteria to be found in wounds treated antiseptically or aseptically. What are the character of these bacteria and where do they come from?
5. What are the best means of surgical disinfection?

The observations as to the relative frequency of the ordinary pyogenic staphylococci and streptococci are not altogether concordant. The yellow staphylococcus appears to be more common in furuncles and abscesses than the white staphylococcus.

The author has found a white staphylococcus in small stitch abscesses and minor grades of inflammatory disturbance in wounds treated antiseptically and aseptically which differs in certain particulars from the staphylococcus pyogenes albus. He suggested that it be called the staphylococcus epidermidis albus. The efforts to differentiate into distinct species the pathogenic streptococci have met with little success. The list of bacilli which may be concerned in suppurative and other inflammatory affections is much longer than was formerly supposed. The bacillus *coi communis* was referred to. The chief interests of the observations being that they furnish an illustration of the possible predisposition to infection afforded by intestinal lesions, and also give an example of the much disputed autoinfection of the suppurative inflammations examined bacteriologically with negative results.

There is reason to suppose that the process of suppuration serves a useful purpose and is one of the most efficient weapons employed by Nature in combating invading microorganisms. Exactly how the abscess formation checks the invasion of bacteria, we do not know.

The quantity of a culture of the staphylococcus aureus required to produce suppuration is not the same for all tissues and all parts of the body. There are also variations in virulence of different cultures of the pyogenic cocci. Inasmuch as it is by their toxic products that the pyogenic bacteria do injury, it is not surprising to find that it makes a great difference in the result whether or not these bacteria enter the tissues already equipped with a reserve force of this poisonous material, or whether it must begin the fight unarmed. This matter of accompanying toxins is possibly of great importance in our understanding of the potentialities of the living agents of wound infection. The differences in virulence found to exist between inflammatory exudates from various sources are much greater than those observed in the cultures of the same bacteria on artificial media.

In regard to the conditions in or about a wound which favor the lodgment and development of pyogenic bacteria, it may be said that anything which interferes with the integrity of the living tissues in a wound is a predisposing cause of suppuration. Chemical irritants, such as carbolic acid and corrosive sublimate, favor the development of microorganisms. A solution of corrosive sublimate as weak as one to two thousand is followed by a distinct line of superficial necrosis. We are not so well informed as to the influence exerted by blood in a wound. Most surgeons lay great stress on hemostasis in surgical operation, while others advise that in certain classes of cases the wound be permitted to fill with blood clot. Is this a source of danger? Fresh blood serum does not possess any such

germicidal power over the pyogenic cocci as it does over the typhoid and many other bacteria. The power of the living tissues to overcome a certain number of pyogenic bacteria is well recognized, and the tendency of modern surgeons is to respect those tissues more and more, not to destroy their vital capacities by the unnecessary application of strong chemical disinfectants, not to bruise them, not to make them too terse, not to strangle them, not to suffer the presence in wounds of spaces and foreign bodies which remove bacteria from the influence of the living fluids and tissues.

Of the various ways in which pathogenic bacteria gain access to wounds, that by contact with infected hands, instruments and other objects, offers the greatest danger. The possibility of infection from the air cannot be ignored. Even in wounds treated aseptically or antiseptically it is not uncommon to find bacteria. The skin may have all sorts of bacteria upon it, but in addition it has its own distinctive bacteria. After the skin has been thoroughly washed and scrubbed the prevailing organism will be found to be the white staphylococcus. This is often found in parts of the epidermis deeper than can be reached by any known means of skin disinfection. We can now understand how, without any flaw in the antiseptic technique of the surgeon, this microorganism may be found present in wounds, and we have here an explanation of the frequent occurrence of stitch abscesses, although the inference should not be drawn that the white staphylococcus is the only bacterium concerned in the production of these annoying complications. How much practical importance attaches to the demonstration of this coccus the author was not prepared to say. The surgeon with good technique who does not bother himself about this coccus in the deeper layers of the skin, is not likely to be severely punished by the behavior of his wounds. Those who put in drainage tubes and other extraneous substances will have to consider it. Some surgeons, on the basis of researches on the bacteria of the skin, have abandoned skin sutures, the edges of the wound being brought together by subcutaneous sutures.

In regard to the methods of surgical antiseptics it was said that the conditions for efficient chemical disinfection have been found to be far more complicated than was formerly supposed, and the substitution wherever applicable of the simple and certain methods of disinfection by heat is to be commended. Chemical disinfectants still have their place for many purposes in the operating room, but their place is not in healthy wounds. Thorough scrubbing of the skin with soap and water by a sterilized brush removes many of the bacteria, but not all, and cannot be regarded as satisfactory means of cutaneous disinfection. Corrosive sublimate accomplishes

much less than is generally supposed. The best results obtained have been by a method in which a saturated warm solution of permanganate of potassium, followed by a similar solution of oxalic acid, plays the principal disinfectant rôle, and this is the procedure now adopted in the gynecological and surgical wards of the Johns Hopkins Hospital.

Dr. ROSWELL PARK, of Buffalo, N. Y.

The study of wound infection is inseparable from that of immunity, and when we have learned that which constitutes or favors immunity we shall approach nearer that which is now a terra incognita. Immunity is a complex condition not dependent upon any single factor, and from pathological interest as well as from clinical importance, our endeavor now must be to analyze the main question of what constitutes or confers immunity, and try to recognize and then solve its various subordinate queries. This statement, too, is inseparable from another, which is to the effect that the surgery of to-day should aim to be aseptic, and not merely antiseptic. In other words, we should abolish sepsis, and not merely aim to antidote it or conquer it when present. The condition of sepsis is a complicated one, consisting of a poisoning by ptomaines, toxins and albumoses having widely different properties. Some of these substances are so antagonistic that one may neutralize the other. In the intestinal canal there are produced poisonous substances which are taken up by the absorbents, but then are filtered out by the liver before reaching the systemic circulation. It is by virtue of this depurative action of the liver that many cases of septical intoxication in surgical patients are avoided. In a division of the general subject of blood poisoning, a condition which may be called intestinal toxæmia or entero-sepsis deserves a distinct place. This occurs not infrequently and may merge into a condition of sapræmia or septicæmia; but, if promptly checked, there is a speedy return to a desirable condition both of wound and patient. . . . By no means do all cases of surgical sepsis have their origin in or about the wound.

We have learned a little in reference to the antagonism of different bacteria and the poisons which they produce. A microbe may enter the system and produce a proteid or albuminose poisonous to the animal, while the introduction of some other substance may neutralize this poison and save the animal. The principle is the same whether the antidotal poison be injected as such, or a second species be inoculated by which it may be produced. Brunton has suggested that blisters do good in this way, by an endermic administration of proteids derived from the blood, but so altered in their passage from the vessels as to have a different effect, and probably by their chemotactic properties. He also suggests that

bleeding may act in a similar manner, as it has been shown that the abstraction of venous blood causes an absorption of proteid matters from the tissues, and these may have an action of their own on the tissues with which they come in contact. The benefits of free purgation probably find here their proper explanation.

The term chemotaxis, to which reference has been made, relates to that faculty possessed by all motile bacteria of moving towards or away from certain substances which seem to attract or repel them. The same power is inherent in the plasmodia of maxomycetes, as well as in various other unicellular organisms; and leucocytes, if not other cells of the human body, possess the same property. Chemotaxis is spoken of as positive or negative, as there appears to be attraction or repulsion. Among the most actively positive chemotactic substances are cultures of bacteria. These are powerfully attracted by the leucocytes. The effect is the same, whether the cultures are alive or have been killed by bottling. The active agent is some product of the life and growth of the bacteria. The leucocytes thus attracted act as scavengers for the surrounding tissue.

These facts have an important bearing upon questions which vitally concern the surgeon. In the light of these researches, it is difficult to see how the possibility of phagocytosis can be denied, and the impossibility of this process looms up in a flood of light when one discusses the phenomena of suppuration or of other kinds of infection, as well as of recovery or immunity therefrom. Support of the phagocyte theory has come from the work of Hankin on "Defensive Proteids." From the spleens and livers of various animals he has isolated the proteid, which has the power of killing bacteria, and he has found that this, while absent from normal blood, could be obtained from the blood of fibrine animals.

The separation of dead and dying matter is a process in which the formation of proteid material figures largely. An important bearing of these facts is on the use of so-called antiseptic agents. The ideal antiseptic is probably blood serum, its parasiticide properties being, in all probability, connected with the existence in it of a globulin which is soluble only in a weak solution of common salt. This may explain the well-known antiseptic action of common salt.

It has been stated that by no means all the sources of sepsis concern the wound itself. The other principal sources of infection may be classified as follows:

1. Previous long-existent toxæmia, as syphilis, diabetes, acetoemia, lithæmia, alcoholism, malaria.
2. Previous anatomical changes which reduce vitality, as inherited diatheses, old age, amyloid change, chronic and acute nephritis.

3. Recent or acute toxæmia, as uræmia, typhoid, intestinal toxæmia, sterconal toxæmia.

4. Other acute conditions, as starvation, scurvy, anæmia.

5. Conditions of environment, as bad hygienic surroundings.

6. Effect of anæsthetics.

7. Effect of antiseptics.

Antiseptics may favor infection in more than one way. Mercurial and iodoform poisoning are not uncommon. When this is established, the case becomes one of acute toxæmia. The wounds may fail to unite, and suppuration may occur again, or the chemical reaction between the vital fluid and the antiseptic may cause a loss of the properties of the antiseptic agent, while the tissues on which it acts may have their constitution so changed as to favor rather than resist infection. Investigations make it appear best to keep all antiseptic agents away from absolutely clean, fresh surfaces. The value of blood serum as an antiseptic has been abundantly shown. This will be poured out in quantity sufficient to serve not only as a cohesive, but as an antiseptic agent. The question here arises as to what is the best antiseptic. It would appear that for most purposes peroxide of hydrogen is the ideal antiseptic, as it not only merely destroys living organisms, but by oxidation of undesirable and infected material, acts as a scavenger of the tissues. We, however, have yet to learn how to utilize to the fullest advantage the properties of blood serum.

Direct infection may be of two varieties, self or auto-infection, and contact infection. The principle sources of contact infection are as follows: 1. Skin and hair. 2. Instruments. 3. Sponges or their substitutes. 4. Suture materials. 5. The hands of the surgeon and his assistants. 6. Drainage material. 7. Dressing material; and 8, Miscellaneous, *e. g.*, drops of perspiration, an unclean irrigator nozzle, the nail brush, the clothing of the operator or bystanders, etc.

The best plan of sterilizing the skin is shaving, followed for a day or two, if there is time, by some antiseptic ointment, properly prepared. The skin should then be washed with *sapo viride* of the German pharmacopœia, with five per cent. of lysol or hydro-naphthol. Then there should be worn until the time of operation a compress, wet with some liquid non-irritating antiseptic, such as creolin or lysol (five per cent.), or hydro-naphthol in saturated cold aqueous solution. At the time of operation there should be a final scrubbing with hydro-naphthol soap, with shaving, and then the skin washed with equal parts of alcohol and ether, or alcohol and turpentine. Where there is not time for this, we must content ourselves with the thorough use of the nail brush, the razor and antiseptic

soap, with the subsequent use of alcohol and ether.

Instruments are best prepared by dry sterilization, as this injured them less than other plans.

In regard to sponges, there is nothing to be added to the well-known directions. It would seem better to use some cheap absorbent material which, after use, could be thrown away.

Silk is best sterilized by placing it in a test tube, then plugging, and keeping for an hour in a steam sterilizer upon two different occasions. Silk-worm gut may be prepared by immersion for a few hours in a one-per-cent. aqueous solution of corrosive sublimate, and then preserving in alcohol. Catgut is best prepared by immersion in benzine or ether to remove fat. It is then dried and soaked for one or two days in a one per cent. watery solution of corrosive sublimate, after which it is dried and transferred to oil of juniper berries, and from this to strong alcohol containing one permille of sublimate. In this, if desired, it can be boiled. It may be chromicised before putting in the oil of juniper.

The hands, even after having been in contact with septic matter, may be sterilized by the following method: Wash with soap and water, using nail brush. Then wash the hands and arms with flour of mustard, as though it were powdered soap. This will remove all odor. Then wash with *sapo viride* (G. P.), to which has been added five per cent. of lysol, creolin or hydro-naphthol. Then rinse, and immerse in a strongly colored solution of permanganate of potassium. They are then rinsed and immersed in a solution of oxalic acid sufficiently strong to decolorize the skin in two or three minutes. The oxalic acid is rinsed off, and the hands may be considered aseptic.

Drainage is probably required only in septic or infected cases.

After an ideal aseptic operation, we need only a sterilized and a protective dressing. In some cases there may be advantage in impregnating the dressing with some antiseptic.

Among miscellaneous sources of infection may be mentioned the use of an unguent applied to the skin to prevent the adhesion of dressings. Experiments have shown that ointments made with even ten per cent. of resorcin or naphthalin, without the application of heat, contain bacteria. The same ointments, heated to the temperature of boiling water, seem to be sterile, and to suffer only from air contamination.

DR. PARK presented the following conclusions:

1. Study of wound infection and of the septic condition thereby produced is inseparable from a study of what constitutes immunity.

2. By a study of immunity is furnished the best clue to a due appreciation of the principles of asepsis.

3. The surgery of the future must aim to be

aseptic, for so far as fresh cases are concerned, we have passed the merely antiseptic era.

4. Asepsis is to be achieved not alone by attention to the wound and the paraphernalia of operation, but by the closest regard to the condition of the patient's organs and tissues.

5. Sepsis may arise from circumstances and conditions other than those pertaining to the wound itself, although hitherto, practitioners have been too prone to scan solely this field when searching for its cause.

6. Sepsis and infection are combatted in more than one way by natural agencies and by inherent properties of cells and fluids totally aside from the measures which the surgeon institutes, and the wisest man is he who studies to take advantage of these vital activities rather than introduce new and conflicting elements from without.

7. A recognition of the power of chemotaxis possessed by organized and unorganized materials in such varying degree can be utilized to great advantage so soon as it can be reasonably clearly defined.

8. A study of chemotactic activity appears to impress one with the truth of the phagocyte doctrine, which if proven, is one having a large bearing upon the principles as well as the practice of the surgery of the future.

9. The proteid material contained within cellular infectious organisms both plays such a rôle in causing chemotaxis as well as in poisoning the animal infected, that we have reason to eagerly welcome all knowledge concerning it.

10. So fast as such proteid material can be isolated, we need among other things to study its effect upon the commonly used antiseptic agents.

11. We need to study much further the antitoxic and bactericidal properties of human blood serum, and the means by which we can avail ourselves of the same.

12. Some such classification as I have attempted to give of the various causes of lowered resistance to infection, or of the causes of vulnerability or susceptibility, will certainly assist in a due appreciation thereof, and will often aid in so fortifying the patient that he may resist infection to which he would otherwise succumb.

13. The condition of enterosepsis, faecal toxæmia, stercoreal intoxication or whatever it may be called, is certainly one which every practitioner has to fear and against which he should assiduously guard. It is not sufficiently generally recognized and combatted.

14. A sub-form of this condition might justly be made and entitled gastro-sepsis, comprising cases where defective stomach digestion often from dilation, brings about a lithæmic or other toxæmic condition which favors infection.

15. Antiseptic agents in the past have worked a revolution in surgical practice and results. We

have now reached a time when we know that they all have their disadvantages and also understand how, if we are strictly antiseptic in our work, we can afford to discontinue their application to wound surfaces.

16. But the insurance of aseptic character of such work, necessitates the use of antiseptic agents of some kind upon everything which may directly or indirectly come in contact with these surfaces.

17. When this work is strictly aseptically performed, the use of drains or further employment of antiseptics, is either an expression of mental uncertainty or of fear. It may be in the interest of humanity, undoubtedly it often is, but it is not attaining the ideal of scientific work.

DR. ARTHUR T. CABOT, of Boston, referred to the debt which practical surgeons owed to the scientific workers. It is the knowledge of how to obtain aseptic wounds that has revolutionized surgery. Reference was next made to the phagocytic action of the cells, and to the germicidal action of the blood serum. The only question is as to which of these processes is distinctly destructive. The bactericidal action of the blood serum has been proved. These observations may serve to explain some of the phenomena in wound fevers. It may be that in erysipelas, the irritation set up by the application of blisters, iodine, etc., may serve to limit the spread of the disease by the action of the blood serum on the micrococci of the disease.

In treatment of wounds, it is desirable to avoid placing animal sutures in the wound. It is better to close all spaces in the wound by pressure. He had found by culture experiments that where the skin, prior to the operation, was free from organisms, yet at the close of the operation their presence could be demonstrated, showing that bacteria had been sown on the wound by the air or otherwise. If necrotic tissue or animal sutures be present, they might constitute a nidus for the development of the bacteria.

MR. THOMAS BRYANT, of London, said that if bacteria are the seed, we must remember that the soil is not of less importance. If the soil is not suitable for the growth of the seed, it will not grow. No surgeon would operate on a patient, except in a case of urgency, until the subject had been prepared for operation. In order to prevent the entrance of the germs, irrigation is of service. For this purpose iodine water, made by adding a few drops of the tincture or solution of iodine to water, is the most valuable. This may be made of a light cherry hue for clean wounds, and of a dark cherry for dirty wounds. It also acts as a good styptic. As a dressing he uses wood wool. The wound is dusted with iodol, 1 part to 1 to 5 parts of boracic acid. In every operation there is a certain amount of molecular death, and drainage is required for thirty-six

hours. Pressure is better than deep sutures for bringing the deeper parts of the wound in contact.

DR. HAROLD C. ERNST, of Boston: While it is true that nearly all forms of suppuration are attended by bacteria, yet it has been shown that a process answering to suppuration can be produced without the action of bacteria. The products of this suppuration, however, do not produce activity when introduced into other animals. It has been shown that some of the agents used to destroy bacteria really favor their growth, by diminishing the chemotactic power of the surrounding tissue cells. Notwithstanding laboratory experiments show the possible occurrence of chemical suppuration, it still remains to be demonstrated that the infection of wounds as seen in practice occurs without the influence of bacterial activity. The most important lessons taught by investigations in this subject are those which warn us that our pupilage is not yet over, and that we are but entering upon the first stage of our knowledge of the processes spoken of here to-day.

MR. JOHN CHIENE, of Edinburgh, said that he had assisted Professor Lister during the whole of his time in Edinburgh. The longer he lived, the more he believed in the work of Lister, and the impress that he had made on surgery. He considered the bacteriological investigations as of the greatest importance, for on these the surgeon must depend in his daily work. Lister long ago spoke of the antiseptic value of the blood clot, but long before, John Hunter pointed out the value of the blood clot. The speaker considered that the spray was of great service. The term "integrity of the tissues" had been used by both speakers, but John Hunter had also laid stress on the vitality of the tissues, which he defined as "the power of the tissues to resist putrefaction." He thought that not only by improving the soil, but by destroying the plant, the best results would be attained.

DR. ARPAD GERSTER, New York, spoke of the many sources of contact infection, and referred especially to infection the result of bad habits on the part of the surgeon. The surgeon may carry out all the details of aseptic and antiseptic treatment, and yet nullify all by a habit he may have of rubbing his nose, his hair or his face; or, as the speaker had seen, placing the knife in his mouth that he might use his hand. An important point in the prevention of infection is clean dissection with the knife, without tearing or bruising the tissues. In regard to irrigation and drainage, he said that these could be eliminated only where the surgeon was absolutely certain of his asepsis, and thought it dangerous for the general practitioner to discard drainage. If he is not certain of his asepsis, he should cling to the older methods, and from these he may ascend to the highest pitch of skill when he can work with real asepsis.

WEDNESDAY, P.M.

DR. P. S. CONNER, of Cincinnati, Ohio, read a paper on

THE LATE MANIFESTATIONS OF SYPHILIS.

More than any other disease, not excepting tuberculosis or cancer, syphilis is the common meeting ground of us all, physicians, surgeons, obstetricians, specialists, pathologists, sanitarians. Modified by transmission through a dozen generations, it is still a dreadful and dreaded ill. Were there only the early lesions, syphilis would take place among the minor ills, and this is the history in the large proportion of cases. Probably in three or four out of five of the acquired cases, the disease is short lived and does but little damage. There is, however, no means of saying in any individual that in a few months or years the disease will be eliminated. Those syphilitic by inheritance suffer from late lesions in far greater ratio than the acquired cases.

There is no sharply defined line between the early and the late constitutional symptoms. Speaking generally the late lesions are neo-formative, the early hardly ever so; so that the gumma is the sign and seal of the tertiaries. Further they are not communicable. As a rule, they are quietly developed. No region or organ is exempt from invasion with resulting new growths. Of most frequent occurrence are the affections of the bones and of the nervous system. The lesion of the bone may be single or multiple. The symmetrical involvement of bones is exceptional. Liquefaction is rarely observed and suppuration only an accident. As ordinarily seen at the present day, extensively destructive and deforming bone inflammations are almost confined to the head and the nasal regions. The reason of this is probably the exposed position of the bones, the thinness of some of them, the abundance of small vessels and the intimate fusion of mucous membrane and periosteum. In the adult and acquired there is seldom difficulty in recognizing the specific character of the lesion.

Though a large proportion of chronic bone and joint disease in the child, the adolescent and the young adult is tubercular, yet the cases in which it is syphilitic are by no means few. This may be recognized by the location of the disease, by recognition of traces on the cornea, the teeth and the skin, by application of the therapeutic test and when practical, by inoculation.

The most frequent and the most dangerous lesions are those of the nervous system. Dr. Horsley in speaking of cerebral gumma, declared that "medicinal treatment in no wise cures and only very temporarily alleviates the trouble. . . . Excision offers the only chance for the patient." Is this the fact? Has not more than temporary alleviation followed the use of the iodides? However great the advances of brain

surgery in the last few years, would not the outlook of the syphilitic be worse than it is, if only in the removal of the gumma could be found a chance of recovery? The affections of motion, sensation and intelligence are frequent in the order given. The first at some time and in some degree is present in every case. Hysteria may mimic syphilis. It is infrequent in men, while brain syphilis is rare in women. In brain syphilis, paralysis is more common than convulsions. Sensation frequently remains unaffected. Disturbance of intelligence are almost necessarily associated with any brain lesions.

In certain cases, although rare, marked motor, sensory and intellectual disturbance occur suddenly and together. Ordinarily after sleep, the patient is found in a state of stupor, from which it is possible to rouse him partially. The muscles are relaxed. The pulse rate is decidedly lessened, the breathing is slow and the temperature is subnormal. Under mercurial treatment, promptly and persistently maintained for many months, relief even permanent may be expected and secured.

Spinal lesions are of infrequent occurrence. Exostoses of the spinal canal may occur and neoplasms develop. There may be pain and paralysis affecting different parts according to the location of the lesion. A question of much interest is the causative relation of syphilis to locomotor ataxia. That the majority of ataxics have had syphilis cannot be questioned. Tabes is certainly not of true gummatous origin, nor can the sclerosis be regarded as the result of the diffused formation so often found in the cerebro-spinal axis, as in other parts of the body. Syphilitic treatment generally fails to cure or even to retard the evolution of symptoms.

There are many things about late syphilis that deserve careful study. What is the explanation of the long years of intermission with the after development of grave functional and organic disturbance? Where has the disease been lurking all these years.

What are the relations of syphilis to other diseases and to injuries? Pre-existing tubercular disease renders probable a more severe and often a more rapid syphilitic course. To the "strumous" individual the specific infection is more dangerous than it is to others. That specific lesions may become tuberculized has been proven, but only rarely does the tubercle bacillus find a nidus in and about a syphilitic new formation. Syphilis is not likely to be inoculated on a person suffering with cancer, and if it is there is no good reason why the two diseases should not each go on in its natural way. On the other hand, cancer may and not so very rarely does attack an area in which there has long been specific thickening and induration, as in the chronic leucomata of the tongue. Once in awhile a gumma

undergoes cancerous degeneration, more often when situated in the tongue than elsewhere. The local affection, no longer amenable to specific treatment, goes on steadily from bad to worse. In certain localities, especially in the breast, a gumma may readily be mistaken for a cancer. If syphilitic growths do not become sarcomatous they often resemble carcinomata, and many reported successful operations for the malignant affection has been really one in which a gumma has been removed.

As a rule the wounds of syphilitics, when the disease is in a latent stage, heal as promptly as in other cases, although union may be delayed or even prevented until after the patient has been brought under the influence of the anti-specific remedies. This is less true of wounds of the soft parts than that of the hard parts, as fractures, where at times false joints will form in spite of the most judicious treatment. When the special lesions are in the process of evolution the chances of interference with proper repair are not few, and no operation should be done at this time which can be postponed. Indeed, at any time before doing an operation, the success of which depends on primary union, it is well to keep the patient for several weeks under the influence of the iodides and mercurials. Very rarely does any wound become actually syphilitic. In one who has had the disease, although there have been no manifestations for years, any traumatism may be the starting point of extensive specific lesions.

In very many cases of aneurism under 40 years of age the lesion may be consequent on syphilis.

The mortality rate of acquired syphilis is rare. In its inherited form the disease is a very grave one. Four-fifths of the pregnancies terminate prematurely.

DR. ABNER POST, of Boston, co-referee: In speaking of syphilis, he spoke from the standpoint of the clinician and student, and not from that of the pathologist. He called especial attention to what is known as late hereditary syphilis. This relates to those who have inherited the disease, and only after a lapse of years show symptoms corresponding to the tertiary symptoms of acquired syphilis. The later forms of acquired syphilis are not necessarily a part of the case. The so-called late lesions occur much earlier in the history of the disease than we are in the habit of thinking. After the third year, the chances of a recurrence grow steadily less. As a preventive of late symptoms, early treatment by mercurials must be ranked high, but no method will allow us to promise a cure that is absolute immunity from subsequent attacks.

The different systems were taken up in order. Induration and enlargement of the lymphatic glands is one of the common symptoms of early syphilis. In late hereditary syphilis the part played by lymphatic is great.

Cutaneous lesions are second in frequency to the lesions of the nervous system in late acquired disease.

Diseases of bones were next referred to. A difference between tuberculosis and syphilis lies in the preference of syphilis for the long bones and their shafts, while tuberculosis attacks by preference such bones as those of the wrist and ankle. Disease of the joints are at times undoubtedly the result of syphilis.

Reference was next made to intestinal and gastric symptoms in syphilitics. It is fairly well established that very serious lesions of the gastro-intestinal tract may take place. As one of the possible causes of disease of the ileo-cæcal valve, syphilis must be given a certain amount of consideration.

In diseases of the nervous system there is a large field which lies practically unexplored in congenital syphilis.

An interesting question is, How much influence should a negative history have in a doubtful case? There are many cases in which the existence of syphilis is not known by the patient.

Every prognosis must be a matter of special consideration. It is the persistence of the damage, and not the specific lesions, that cause the persistence of the symptoms. There is something to be deduced in the matter of treatment. Anti-syphilitic treatment has great power over the active process of late lesions, but it is powerless to restore the tissue already destroyed. The attempt to destroy a syphilitic tertiary sore is in general futile. The late lesions of inherited syphilis are as readily controlled as those of acquired disease. The amount of iodides that may be administered is very large. In regard to treatment as an aid in retrospective disease, too much value must not be placed upon this element in doubtful cases, for mercurials and iodides do have some influence over tuberculosis.

The study of syphilitic phenomena is a necessity of medical progress. The possibility of syphilis renders uncertain the diagnosis of tuberculosis and cancer, and other malignant forms of disease. We need the most careful clinical studies; we need hospitals specially devoted to syphilis; we need to make its study obligatory.

The subject was further discussed by DR. ROBERT T. EDES, of Washington, and DR. JAMES NEVINS HYDE, of Chicago.

THURSDAY, SEPTEMBER 24.

The discussion on "Fibroid Processes (chronic interstitial inflammations, sclerosis), their Pathology, and Etiology, with especial reference to the Influence of Diathesis and Heredity," was opened by DR. A. L. LOOMIS, of New York.

Fibroid processes cannot be spoken of as degenerations, for they imply an active process, productive in character. There is always a

higher than normal grade of activity in those elements which develop connective tissue. The only way in which fibroid tissue can develop is from growing cellular elements. He excluded from the list of true fibrosis all conditions of simple preponderance of fibroid tissue from the atrophy of other elements. Two forms of fibrosis were described at length, the hyperplastic and the inflammatory. The first is due to diminished nutritive supply, to parenchymatous atrophy, to nuclear proliferation and to connective tissue hyperplasia. The inflammatory form is due to parenchymatous degeneration, to constitutional influences, and to local attraction by the products of tissue change, positive chemotaxis.

All those agencies which diminish the vital forces by which the cell appropriates to itself its proper elements, tend to the production of fibrosis. These agencies may be mechanical, chemical or mental. Among the causes of fibrosis may be mentioned direct stimulation of fibrous growth, all conditions including a limited degree of nutritive supply, all conditions and elements which induce perverted nutrition, either degeneration or necrosis, including mechanical forces, perverted or defective nutritive supply, and all toxic and trophic influences.

The relations between diathesis and fibroid processes were next considered. A diathesis may manifest itself by any bodily function displaying an activity out of proportion to the stimulant applied. In the fibroid diathesis, the growth of fibroid tissue is out of proportion to the amount of stimulation. Fibroid processes are not always injurious, as is seen in cases of cured tuberculosis. In seventy cases of cured tuberculosis under the observation of the writer, fifty-four presented well-marked evidences of fibrosis. Diathesis often determines the nature or prominent action which will follow any given irritant or stimulation, provided more than one is possible. It also modifies the ratio between the established process and its causes. The speaker next referred at length to the special manifestation of the fibroid process in the arteries, heart, kidney and liver.

DR. WILLIAM OSLER, of Baltimore, considered the fibroid processes under the head of degenerative, inflammatory and developmental. The degenerative were subdivided into the atrophic, the secondary degenerations, the toxic forms, as from lead, ergot, syphilis, the sclerosis associated with similar changes in the smaller arteries and capillaries. The degenerative form includes the greatest number.

The inflammatory form was subdivided into the secondary forms, in consequence of reactive inflammation following hæmorrhage, tumors, foreign bodies, abscess and trauma; the sclerosis which follow primary encephalitis or myelitis.

The following questions were suggested for consideration:

1. What is the relation of vascular change to the degenerative sclerosis? How far histologically are they mesodermal or ectodermal; or are they mixed, containing both neuroglial and collagenous connective tissue?

2. The lobar scleroses of children. What is the nature of the primary affection? Is it inflammatory, an encephalitis or meningo-encephalitis; or is the essential lesion in the vessels?

3. Developmental. Can we recognize a purely ectodermal form?

DR. CHARLES L. DANA, of New York, referred to the chronic fibroid processes of the spinal cord. He classed these into, first, primary degenerative; second, secondary degenerative; and third, reparative and inflammatory. The first includes locomotor ataxia, lateral sclerosis, combined sclerosis, progressive muscular atrophy and amyotrophic sclerosis. These sclerosis are not inflammatory, but due to the destruction primarily of cells and fibres. The causes of this degeneration were either toxic substances, or disturbance of nutritive equilibrium by infections, vascular strain or imperfect nutritive supply. They are not related to any special diathesis.

The secondary fibroid processes, so-called, have been shown by French pathologists to be probably in great extent neuroglial proliferations or gliosis, not a fibrosis.

The inflammatory scleroses, including chronic myelitis, diffused myelitis and transverse myelitis, are mixed processes composed of a simple necrotic process, inflammatory processes and secondary degenerations.

DR. WILLIAM COUNCILMAN, of Baltimore, referred to the fibroid process as found in the liver, giving the results of investigations made in the Johns Hopkins Hospital. He dwelt upon the fact that the first element in the fibroid process was a necrosis. The fibrosis is not the result of stimulation. The tendency to growth is always present, and as soon as the opposition is removed, it manifests itself.

The Congress then adjourned *sine die*.

American Surgical Association.

The twelfth annual meeting of the Association was held in Washington, D. C., September 22, 23, 24, and 25, 1891.

TUESDAY—FIRST DAY.

The Association was called to order by the president, DR. CLAUDIUS H. MASTIN, of Mobile, Ala., who delivered the presidential address.

The next paper was read by DR. D. HAYES AGNEW, of Philadelphia, an abstract of which follows:

PRESENT STATUS OF BRAIN SURGERY BASED ON THE PRACTICE OF PHILADELPHIA SURGEONS.

What is the present position of brain surgery and what practical lessons can be deduced from a review of the recorded results in this department of surgery? The object of the author was not to glean the entire field but to confine himself to the work done by Philadelphia surgeons in trephining for epilepsy traumatic and Jacksonian intra cranial abscess, hæmorrhage, hydrocephalus, cephalalgia, microcephalus and neoplasms.

Traumatic Epilepsy.—Fifty-seven cases were recorded. Of this number forty-one recovered from the operation, four died and of twelve the result is not given. Thirty-two experienced temporary relief, nine obtained no benefit, four passed out of observation and four were operated on too recently to permit of the result being determined, and four are reported cured. In one of the cases reported cured, the patient had been free from attacks for twenty-eight months. In two, for ten months, and in the fourth, a branch of the great occipital nerve was found imprisoned in the bone cicatrix. While the results in these cases have not been satisfactory, it by no means follows that surgery holds out no hope against epilepsy. It is not saying too much to assume that surgery is responsible for the great majority of traumatic epileptics, though this statement does not by any means criminate the surgeon of an early day. Whenever the profession can accept the doctrine that all depressed fractures, however slight the depression, and entirely irrespective of pressure symptoms, are proper subjects for trephining, then will traumatic epilepsy largely disappear from the list of surgical diseases. It is not improbable in view of the greatly diminished risk of trephining, that the operation will be extended even to cases of simple fracture or fissure of the skull.

Jacksonian Epilepsy.—The table contains fourteen cases. In all the discharging centre was removed. Nine recovered and four died. Of those recovering, three had less frequent and less violent attacks. One realized slight benefit; one disappeared shortly after operation, and in two no benefit was observed. One is reported as cured, and in that case the operation was done during the present year.

Abscess.—Eighteen cases of this nature have been collected. Six had had fracture of the skull; two had syphilitic necrosis. In one a foreign body had entered the brain; in nine the abscess was due to middle ear disease and in two there had been a severe blow without fracture of the skull. All the patients died within less than fourteen days.

Five cases of trephining for intra-cranial traumatic hæmorrhage are recorded. In each instance the symptoms necessitating operation developed

within twelve hours after the reception of the injury. Four of the five cases recovered not only from the operation, but with the restoration of the suspended functions.

Of trephining for acute and chronic hydrocephalus, five cases are reported. All the cases died, one living to the forty-fifth day. As hydrocephalus is usually due to tubercular disease or to morbid growth, it is difficult to understand on what ground such operations are undertaken.

Cephalalgia.—Five cases are given in each of which the focus of pain was referred to the neighborhood of a scar on the scalp. In four of the cases complete relief was afforded.

Trephining for Microcephalus.—Seven cases are reported, of which four died and three recovered from the operation. One of the deaths, however, was due to scarlet fever occurring shortly after the operation. The result in the successful cases is reported as "moderate improvement." From the results obtained from the education of idiots, the author thought it wiser to relegate these unfortunates to special training schools rather than to the trephine and rongeur. The debatable cases would be those accompanied with athetosis, in which condition some improvement might be obtained.

Brain Tumors.—Only four operations for brain tumors have been done by Philadelphia surgeons. In one the growth was a fibroma weighing four ounces. The operation was done by Dr. Keen, December 15th, 1887, since which time the patient has had only six epileptic seizures. In the second case done by the same operator the tumor was in the occipital lobe and not removable. The patient died the following day from shock and hæmorrhage. In the third case no tumor was found, and in the fourth a cyst occupying the cuneus was found and emptied. The patient died in thirty-six hours and at the autopsy a large sarcoma was found occupying the temporal sphenoidal lobe.

The deductions presented by the author are as follows:

1. That all fractures of the skull attended with depression, however slight, and entirely irrespective of symptoms, should in view of the late after effects be subjected to the trephine.
2. That trephining for traumatic epilepsy promises only palliation at best.
3. That trephining for Jacksonian epilepsy is to be regarded as only affording temporary benefit.
4. That trephining for abscess in view of the fact that all such cases left alone almost invariably terminate fatally is entirely proper, and that the earlier such operation is done the better.
5. That trephining for intracranial traumatic hæmorrhage is both an imperative and highly promising operation.
6. That, medical measures having failed, tre-

phining for cephalalgia, or traumatic epilepsy, should be undertaken with every prospect of success.

7. That trephining for hydrocephalus is a useless operation.

8. That trephining for microcephalus, independent of athetosis, confers no credit upon surgery.

9. That it is more than probable as our observations multiply, the sphere of the trephine as a preliminary for the removal of brain tumors will be lessened rather than be amplified.

DR. JOHN CHIENE, of Edinburgh, did not take the same depressing view in regard to traumatic epilepsy. He referred to three cases in which decided benefit had followed operation. He agreed fully with what had been said in regard to operation in depressed fracture whether symptoms be present. As regards methods, he spoke of simple measures for locating the fissure of Rolando. The upper extremity may be located by means of a piece of string being one-half inch behind the middle. The angle may be secured by folding a square piece of paper into four, around one of the angles. Three of these parts will give the proper angle. The purification of the scalp is a difficult matter, but may be accomplished by shaving and soaking with carbolic lotion for three days. For opening the skull he advised, as safer than the trephine, the gouge and mallet. For enlarging the opening, the gouge-forceps fill a useful purpose. For puncturing the dura and the brain, he uses a Graefe knife. Hæmorrhage from the brain may be checked by plugging with a match; bleeding from the brain, by hot water. Stress was laid upon the necessity of constant watching of brain cases, and illustrative cases cited. In one case of supposed injury to the head (but which later proved to be a case of apoplexy), in which the patient was in a dying condition, great improvement, eventuating in practical recovery, followed trephining.

DR. W. W. KEEN held that every case of depressed fracture should be operated upon, even in young children. A blow upon the head not sufficient to cause fracture may produce laceration of the dura or of the cortex. In regard to linear fracture, however, he was disposed not to accept the view that operation should be performed. In regard to tapping of the ventricles, he thought that further experience and an improved technique would lead to better results. In epilepsy he suggested the use of the bromides after operation had been done. In many cases of brain tumor, where there is no hope of removing the growth, great comfort may be afforded the patient by removal of bone.

DR. CHARLES B. NANCREDÉ, Ann Arbor, reported cases in which cure had followed operation for traumatic epilepsy. In one the cure

was of ten years' duration. Often cases that are reported as failures soon after the operation prove to be cures when followed for a longer time. The operation removes only one of the elements that is causing the epilepsy. In speaking of these operations, he stated that hæmorrhage from the skull could be checked by forcing in the diploe. In regard to simple fissured fracture, he asked how the diagnosis could be made.

DR. ROSWELL PARK, Buffalo, differed from the author as regards the results of operations for epilepsy. He had himself had cases in which decided benefit was afforded. In order to determine the effect, time must elapse, so that the epileptic habit may disappear. The operation removes the anatomical cause, but ordinary therapeutic measures are needed to counteract the secondary conditions. Reference was also made to the relief afforded in brain tumors, even where the removal of the growth was not contemplated. He reported two cases of craniotomy for microcephalus in which benefit had followed.

DR. H. C. WOOD, Philadelphia, thought that we should wait before coming to any conclusions as to the result of treatment, either medicinal or surgical. He referred to one case in which, under medicinal treatment, the attacks remained absent for seven years, and then returned. He advised that in these cases, before the contemplated operation was performed, a mock operation should be done, and the effect noted. He cited cases in which such measures had been followed by benefit.

DR. J. J. PUTNAM, Boston, thought that a simple, smooth, depressed fracture would not be likely to cause any symptoms. The irritation from a sharp spicule of bone probably will cause irritation. Probably the most important element in the causation of trouble is the results of the original injury to the cortex. The interstitial changes in the cortex take the form of sclerosis, and it seems *a priori* doubtful that removal of the bone would materially affect it. The operation may not prove indifferent, for the cicatrization of the incised may lead to harm.

MR. THOMAS BRYANT, London, had been much struck with the emphasis with which Professor Agnew had insisted upon the treatment to be followed in depressed fracture. As a practical rule, he was disposed to agree with him; but there are certain exceptions. He did not think it wise to encourage practitioners to trephine and elevate every case of depressed fracture. He could recall many cases of depressed fracture, followed for years, in which no symptoms followed. Depression of the lateral aspects of the skull are not so apt to be followed by symptoms as depression of the vault of the skull. From these remarks, he said, it would naturally follow that he disagreed with the observation that in

every case of fissure of the skull operation should be done. He wished Dr. Agnew had gone more thoroughly into the reason for this statement. If there had been no brain symptoms, although the blow may have been sufficient to cause fracture, it would not be wise to insist that we should at once proceed to explore to see if there is fracture. It is better to wait and watch for symptoms, being ready to operate as soon as there is a suggestion of something wrong. Although the risk of exploratory operation may be slight, yet it must be admitted that it is attended with some danger.

DR. D. HAYES AGNEW, in traumatic epilepsy, did not condemn operation, but curative results should not be expected from it. Its result is only one of amelioration. He could not withdraw his statement made in the paper, for in many of the cases of traumatic epilepsy there has been no history of unconsciousness or other symptom. There has been a blow on the head, and many years later epilepsy has appeared. It is impossible to determine the condition of the internal table of the skull by inspection of the external table. He had seen a simple crack in the skull, with the internal plate forced downwards some distance.

A paper on "Resection of the Wrist," by DR. RAFAEL LAVISTA, of Mexico City, Mexico, was presented and read by title.

Report of a committee on the

RESULTS OF TREATMENT OF SIMPLE FRACTURE OF THE SHAFT OF THE FEMUR,

Read by STEPHEN SMITH, M.D., of New York.

At the meeting of the American Surgical Association, held May 15, 1890, the following preamble and resolution was adopted:

WHEREAS, in the treatment of fractures of the shaft of the femur, the question often arises as to what is a satisfactory result in a given case; therefore,

Resolved, That a committee be appointed by the President, to report at the next meeting of the Association, what, in their judgment, under the methods of treatment, should be considered as satisfactory results.

The following committee was appointed: Dr. Stephen Smith, New York; Dr. D. Hayes Agnew, Philadelphia; Dr. David W. Cheever, Boston; Dr. D. W. Yandell, Louisville; Dr. Chas. T. Parkes, Chicago; Dr. P. S. Conner, Cincinnati; Dr. Charles B. Nancrede, of Ann Arbor, and Dr. Hunter McGuire, Richmond, Va.

The question referred to your committee has an important bearing upon the jurisprudence of surgical practice. One of the most frequent causes of prosecution of surgeons is the alleged mal-treatment of fractures of the femur.

The following circular was sent by the committee to the members:

"What should be considered as a satisfactory result (other than perfect union) in the treatment of a simple fracture of the shaft of the femur?"

The committee has reviewed the several questions raised and endeavored to secure a common ground on which the Association can take its position, and on which members can individually stand before the courts.

1. Bony union: The necessity of firm bony union does not admit of discussion. The amount of callous should not be taken as a criterion of the success of treatment.

2. Relation of long axis of the fragments: While it is the aim of the surgeon to restore the normal relation of the long axis of the fragments, yet it is generally impossible to secure exact apposition of the fractured surfaces, nor can the normal long axial line be restored with mathematical precision.

3. Correspondence of the anterior surfaces of the fragments: On this depends the position of the foot. The result of treatment, to be satisfactory, requires that the anterior surface be in the same planes.

4. Length of limb: This was formerly regarded as the test of success of treatment. The records of the past show that shortening was the universal rule. The discovery of the natural discrepancy in the length of the lower limbs has considerably modified our estimate of this test. Ninety per cent. of healthy, uninjured persons have lower limbs of unequal lengths. In thirty-five and eight-tenths per cent. the right limb is the longer; in fifty-four and three-tenths per cent. the left is the longer. If the amount of shortening does not exceed the average natural difference in the length of the limbs—viz., about one-half an inch—the result will be in accordance with the laws of nature in the conformation of the lower extremities. If the shortening does not exceed the extreme limit of difference in the lengths of the natural limbs—viz., about one inch—the result should be considered satisfactory. An unsatisfactory result as regards shortening exists only when the amount of shortening exceeds one inch.

5. Lameness: This is a symptom of variable importance. Some will have a limp with one-fourth inch shortening, while others will not limp with one-half or one inch shortening. In many cases the limp disappears with time, or if it continues it is the result of careless habits of the patient.

6. Restoration of function: Essential to the function of the femur is strength of the femur at the seat of fracture, free and unimpeded action of the muscles, and proper motion of the knee joint. The determination of the degree of restoration of function cannot be made for at least one year after the cessation of treatment.

7. Conditional results: There is a class of cases in which our estimate of results must be based upon a careful study of the special circumstances connected with the treatment of each case.

Results widely different from those already given must be regarded as satisfactory, when we consider the circumstances under which the treatment is necessarily pursued. The treatment may have been conducted under circumstances in which it was impossible to secure proper apparatus, or the injury may have involved other parts so as to prevent the patient from taking the necessary position, or the patient may have suffered from delirium or other malady.

The following conclusions were presented:

A satisfactory result has been obtained in the treatment of fracture of the shaft of the femur when—

1. Firm bony union exists.

2. The long axis of the lower fragment is either directly continuous with that of the upper fragment, or the axes are on nearly parallel lines, thus preventing angular deformity.

3. The anterior surface of the lower fragment maintains nearly its normal relation to the plane of the upper fragment, thus preventing undue deviation of the foot from its normal position.

4. The length of the limb is either exactly equal to that of its fellow, or the degree of shortening falls within the limits found to exist in ninety per cent. of healthy limbs, viz., from one-eighth of an inch to one inch.

5. Lameness, if present, is not due to more than one inch of shortening.

6. The conditions attending the treatment prevent other results than those obtained. Adjourned.

WEDNESDAY MORNING.

DR. A. G. GERSTER, of New York, read a paper on

ASEPTIC AND ANTISEPTIC DETAILS IN SURGERY.

Personal cleanliness and cleansing of the field of operation are to be accomplished by mechanical measures, rather than by disinfectants. The dirt and oily matter of the skin is removed by emollient potash soap and stiff brush. This is followed by the germicidal lotion. The hands of the surgeon may be sterilized in the following manner: The nails are trimmed short, the hands scrubbed with soap and brush in hot water for one minute. The nails are then cleaned, and the hands immersed in strong alcohol, and then washed in 1:1,000 corrosive sublimate solution. Brushes require careful attention. They may be sterilized by boiling for five minutes in water containing 1 per cent. of washing soda. They should be kept in 1:1,000 bichloride solution.

Instruments are sterilized by boiling for five minutes in soda solution, in a covered vessel. The addition of the soda prevents formation of rust.

Dressings are rendered absorbent and sterilized by steam. Strong antiseptic agents in dressings are objectionable from their action on the spine.

Dressings may also be sterilized by boiling in soda or potash lye.

The use of Florida sponges was recommended, as, owing to their cheapness, they can be used once and then thrown away. Boiling of sponges is to be condemned. Sponges are best prepared by heating, followed by immersion in dilute muriatic acid. Acid is removed by washing, then immersed in water for two days to permit the spores to germinate. Each sponge is then kneaded in hot water for one minute with potash or soft soap. They are then placed in 5 per cent. carbolic acid solution for twenty-four hours. As a substitute for the large flat sponge used in laparotomy, he recommended the use of pads of absorbent gauze.

In operating few instruments, sponges and assistants should be employed. The dissection should be clean, the tissues being cut rather than torn. Irrigation should not be employed except when special indications present. In the abdominal cavity irrigation was condemned. When the peritoneal cavity is contaminated by pus, etc., simple wiping away of the matter is sufficient.

In perfectly aseptic operations, no drainage is required. Iodoform gauze can often be substituted for the use of tubes. Drainage by tubes is required where there is progressive suppuration.

In combating septic morbid processes, mechanical measures, such as incision, drainage and irrigation, are of more importance than chemical measures.

DR. J. COLLINS WARREN, Boston, described the details of operative surgery as practiced in the Boston city hospital, the Massachusetts general hospital and the children's hospital.

DR. J. WILLIAM WHITE, Philadelphia, thought that the time had not yet arrived when the use of antiseptics could be dispensed with. He preferred an antiseptic dressing in all cases except where the wound is absolutely sterile, and where no discharge is to be expected. While in a general way he agreed as to the value of mechanical measures in cleansing the skin, he saw no good reason for throwing aside entirely the use of the weaker chemical solutions. There are so many cases in which we cannot be sure that the wound is aseptic, antiseptic dressings become of importance. He had tried the gauze substitute for sponges in abdominal work, but found it objectionable from the fact that when the gauze remains long in contact with the intestines, threads of the gauze adhere to the intestine.

DR. JOSEPH RANSOHOFF, Cincinnati, said that in some cases it was absolutely impossible to render the part aseptic, and cited cases illustrating this point. In cases where it becomes clear that the wound is infected, he removes the dressings, and soaks the part in hot water. He had discarded the use of sponges altogether. In the majority of cases he employs the aseptic dressing,

but could see no harm in the use of antiseptic dressings. Dressings, etc., in private practice may well be sterilized by heating in the oven. He thought that tight closing of the wound should be practiced oftener than it now is. Drainage is rarely used except in wounds already septic. He often uses catgut for drainage. In the septic cases he thought that probably the surgeon was often responsible for the infection of the wound. By clean incisions, cutting far away from the disease, and by not using the sharp spoon too freely, infection of the wound in suppurating cases can often be prevented.

DR. E. M. MOORE, Rochester, asked what objection was there to irrigation. In amputations, for instance, irrigation with 1:1000 bichloride solution affords a ready means of removing clots, etc. The clots are removed, and the wound can be left in a dry state. If this irrigation does no harm, why not use it? Dr. Gerster had condemned it, but he had not given his reasons for such condemnation. In certain cases of abdominal section, especially where there was oozing of blood, the use of hot irrigations of aseptic water were of great service.

DR. GERSTER, in concluding, said that he did not condemn antiseptic methods. He employed both methods. In its proper place, asepticism is infinitely superior to anti-septicism, but the cases must be properly selected. Teachers must be careful not to go too far in advance of the rest of the profession. Those who have not learned the detail should be warned to stick to the older methods, gradually approaching the higher.

DR. J. WILLIAM WHITE, of Philadelphia, read a paper on

THE SURGERY OF THE SPINE.

The conditions discussed were: Congenital deformities; tuberculosis of the spine; neoplasms and traumatisms. Under the first head, spina bifida is the only condition requiring consideration. In this, injection by an iodo-glycerine solution offers the greatest prospect of ultimate recovery with the least immediate danger. In tuberculosis of the spine the indications for interference are the evacuation of pus, removal of a sequestrum or of a focus of carious bone, and relief of the cord from pressure. There are records of fourteen operations upon the bodies of vertebrae for abscess, with eight cures, five cases improved, and one death, which had no relation to the operation. There have been forty cases of operation on the spine for the relief of pressure. In twenty-two there was either improvement or cure. The effect of suspension in the treatment of Pott's paralysis has been so favorable that it should occupy a prominent position.

Conclusions in regard to operative treatment

of spinal tuberculosis with symptoms of pressure on the cord were:

1. The paralysis in Pott's disease is not, as a rule, due to a transverse myelitis or hopeless degeneration, and is not usually due to the pressure of the carious or displaced vertebrae, but is, in the majority of cases, the result of an external pachymeningitis which results in the formation of an extra-dural connective tissue tumor.

2. Speaking generally, a favorable prognosis is to be given, especially in children, in cases of Pott's paralysis in which the abscess, if any exists, can be evacuated; the treatment by extension, and with plaster jacket, can be employed and the patient can be put under the most favorable hygienic conditions.

3. In cases in which all this has been tried unsuccessfully, or in those in which the disease is slowly but steadily progressing to an unfavorable termination, where with more or less complete loss of motion and sensation below the level of the lesion there are incontinence of urine and feces and the development of bed-sores, and especially when acute symptoms threaten life, resection becomes entirely justifiable.

4. Operation having been decided upon for any or all of the above reasons, the prognosis will be favorable in direct proportion to the youth and strength of the patient, the absence of generalized tuberculosis, and the nearness of the lesion to the base of the sign.

5. When the tuberculous process affects the arches and there is paraplegia, we may sometimes operate, hoping not only to free the cord, but at the same time remove the focus of disease. This double indication may also be fulfilled in those cases where, without bony disease, there is posterior pachymeningitis or a tuberculoma occupying the canal.

6. If the lesion of the bodies of the vertebrae is in the lumbar region at a point where these bodies are accessible, it might be possible in certain cases to expose the cord from the back, by removal of the laminae, with the object not only of removing pressure but of reaching and taking away the diseased bone and tubercular granulation.

7. In tuberculosis of the body of a vertebrae and compression of the cord by anterior pachymeningitis we can fulfil only one indication—liberate the cord from the pressure. We should operate only in grave cases when acute compression, the appearance of respiratory complications, the rapid development of degenerative processes force us to interfere, or where the course of a chronic case is steadily toward a fatal termination, although no advanced visceral tuberculous lesions are present.

In regard to neoplasms it was said that every case of focal spinal lesion thought to depend on a tumor, and not distinctly a malignant and gen-

eralized disease, should be regarded as amenable to operative interference, no matter how marked the symptoms of pressure may be, nor how long continued.

Traumatism.—The indications and contraindications for trephining in spinal fractures are based on the following points:

1. The nature of the vertebral lesion and the nature and extent of the medullary lesion.

2. The time which has elapsed since the traumatism.

3. The regional level of the medullary lesion.

The following conclusions were presented:

1. Some objection urged against operative interference in spinal tranmatism, *i.e.*, hæmorrhage, frequency of absolute destruction of the cord, pressure from inaccessible fragments of bone, etc., have been shown to be unsupported by clinical facts; others were largely due to a well-founded dread of *a*, the shock, in those cases operated on in pre-anæsthetic times; and *b*, consecutive inflammation, supuration and pyæmia in pre-antiseptic periods.

2. Some results of recent operative interference in properly selected cases of fracture of the spine are encouraging, and should lead to the more frequent employment of resection of the posterior arches and laminae; *a*, in all cases in which depression of those portions, either from fracture or dislocation, is obvious; *b*, in some cases in which, after fracture, rapidly progressive degenerative changes manifest themselves; *c*, in all cases in which there is compression of the cauda equina from any cause, whether from anterior or posterior fracture, or from cicatricial tissue; *d*, in the presence of characteristic symptoms of spinal hæmorrhage, extra- or intra-medullary.

3. Operation is contraindicated by a history of such severe crushing force as would be likely to cause disorganization of the cord. The question which will remain in doubt previous to operation will usually be that of the extent of damage done to the cord, and the possibility of its taking on a reparative action. As to this, the safest rule is that which has been formulated by Lauenstein, namely, that if after the lapse of six or ten weeks there is incontinence of urine or incontinence of feces, and especially if there is also the development and spreading of bed sores, but little is to be hoped for from the unaided efforts of nature. If, however, these symptoms are absent, and if there be the least improvement, it will be proper for the surgeon to delay operative interference still longer.

DR. H. H. MUDD, of St. Louis, dwelt upon the importance of remembering the liability to severe shock in these spinal operations. He reported three cases of bullet wounds of the spinal column, one of which ended fatally.

DR. JOHN B. ROBERTS, of Philadelphia, insisted that injuries and diseases of the spine, of a

surgical kind, should be treated as we treat injuries of the cranial cavity. Cases of Pott's disease with angular curvature have been referred to, but sufficient stress has not been laid upon the fact that many of these cases with motor paralysis improve under ordinary remedies, the inflammatory exudation being absorbed. In traumatism of the spine, we should explore the spine as we should explore the brain. In severe injuries with fracture, spiculæ of bone are often driven down on the canal.

DR. J. J. PUTNAM, of Boston, thought that the dangers of inflammation had not been sufficiently dwelt upon. Some cases of spinal injury, in from one to four years, show some improvement. In such cases, an operation may add to the improvement.

DR. JAMES McCANN reported two cases of spinal injury in which operation had been performed. In one death followed. In the other there was great improvement.

DR. N. SENN, of Chicago, read a paper on
THE TREATMENT OF TUBERCULOSIS OF BONES
AND JOINTS BY PARENCHYMATOUS AND
INTRA-ARTICULAR INJECTIONS.

The following conclusions were presented:

1. Parenchymatous and intra-articular injections of safe anti-bacillary substances are indicated in all subcutaneous tubercular lesions of bones and joints accessible to this treatment.

2. Of all substances so far employed in this method of treatment, iodoform has yielded the best results.

3. The curative effect of iodoform in the treatment of local tuberculosis is due to its anti-bacillary effect, and its stimulating action on the healthy tissue adjacent to the tubercular product.

4. A 10 per cent. emulsion in glycerine or pure olive oil is the best form in which this remedy should be administered subcutaneously.

5. The ethereal solution should never be employed, as it is liable to cause necrosis of the tissues overlying the abscess, or iodoform intoxication.

6. Tubercular abscesses and joints containing synovial fluid or tubercular pus should always be washed out thoroughly with a three to five per cent. solution of boracic acid before the injection is made.

7. Injections should be made at intervals of one or two weeks, and their use persisted in until the indications point to the cessation of tubercular inflammation and the substitution for it of a satisfactory process of repair, or until the result of this treatment has shown its inefficacy and indications present themselves of the necessity of resorting to operative interference.

8. If the treatment promises to be successful, symptoms pointing to improvement manifest themselves not later than after the second or third injection.

9. In tubercular empyema of joints and tubercular abscess, gradual diminution of the contents of the joints or abscesses at each successive tapping and lessening of the solid contents of the fluid and increase of its viscosity, are the conditions which indicate unerringly that the injections are proving useful, and that in all probability a cure will result from their further use.

10. Moderate use of limb is compatible with this method of treatment, provided the disease has not resulted in deformities which would be aggravated by further use of the limb. In such cases, correction of the deformity should be postponed until the primary joint affection has been cured by the injections.

11. Parachymatous and intra-articular medications, with anti-bacillary material, has yielded the best results in tubercular spondylitis, attended by abscess formation and tuberculosis of the knee and wrist joints.

12. This treatment may prove successful in primary osseous tuberculosis, followed by involvement of the joint, provided the osseous foci are small.

13. Extensive sequestrums of articular ends, with secondary tubercular synovitis, always necessitates resection, but preliminary treatment by iodoform injections into the affected joints constitutes a valuable preparatory treatment to the operation, and adds to the certainty of a favorable result.

14. In open tubercular affections of joints, incision, scraping, disinfection, iodoformization, iodoform gauze tampon, suturing and subsequent injections of iodoform emulsion is advised, and yields excellent results, and should be employed in all cases in which a more formidable operation can be avoided.

15. Balsam of Peru ranks next to iodoform in the treatment of tubercular affections of bones and joints, and if the latter remedy, for any reason, can not be employed, or has failed in affecting the desired result, it should be given a fair trial, if operative treatment is not urgently indicated.

(To be concluded.)

NECROLOGY.

David Humphreys Storer, M.D., LL.D. and
Ex-President.

This estimable and honored physician and scientist has passed away, *ad majores*, ripe in years and character. He was, with one exception, the senior surviving president of our Association. He presided in 1866, being the immediate successor in office of the Nestor, Davis, who held the chair at the second Boston meeting, in 1865. The convention over which Dr. Storer presided was held at Baltimore, the first southern city to entertain our organization after the signature of peace and the

healing up of intertuecine wounds had begun in good earnest. Dr. Storer was born at Portland, Maine, March 26, 1804, and in that city received his early training. He was an alumnus of Bowdoin College, of the class of 1822, graduating at the early age of eighteen. In 1876 that same institution conferred upon him a doctorate in laws. He studied medicine with Dr. John C. Warren, of Boston, obtaining his medical degree from the Harvard School in 1825. Five years later he, with Drs. Oliver Wendell Holmes, Jacob Bigelow and one or two others, founded the private medical school which was known as the Tremont Street School, and which was a pioneer in that kind of systematic tuition and drill of students. This school was a gain to the cause of medical education in that vicinity, and was one of the incentives to the subsequent establishment of a summer term in the medical department of Harvard. He likewise assisted in the formation of the Society of Natural History, and for years gave to it freely of his evening hours, and to the subjects of natural history much interest and research. To the department of ichthyology, especially, he contributed some valuable memoirs. In 1837 his scientific repute was such that he received a state appointment to report upon the zoology and herpetology pertinent to the then closing State survey. In 1845 he contributed to the New Haven meeting of American Naturalists his standard synopsis of the fishes of North America; and later he brought out his illustrated quarto on the "Fishes of Massachusetts." He became a visiting physician to the general hospital of the State in 1849, served for nearly a decade, and was then promoted to a consultant's position, which he retained over thirty years.

His membership in the Massachusetts Medical Society dates from 1829; and he was the Senior Fellow residing in Boston at the time of his decease. He delivered the annual discourse before the Society in 1851, taking for his subject "Medical Jurisprudence;" and this was the same subject-matter that a few years later made a part of his chair in the Harvard Medical School. He was in his fiftieth year when he was chosen to succeed Dr. Walter Channing as professor of the theory and practice of obstetrics and medical jurisprudence. This chair was filled by him acceptably and eloquently from 1854 to 1868. His lectures were seldom shirked by the students, but on the contrary they added popularity to the college. He was dean of the school for nine years. In 1868 his active participation in college duties ceased by resignation. His interest in the Association was early enlisted, and he attended a majority of the meetings in the first decade of its history, being made one of the vice-presidents in 1855. He was especially prominent in the proceedings at the Charleston Convention when the question of Dr. Ramsey's obstetrical statistics was made a cover for an attack upon the Association. He was at that time the chairman of the Committee on Obstetrics, the branch of medicine which, with the diseases of women, engaged his special attention. He was one of the few who were made honorary members of the American Gynecological Society, at its foundation in 1876. He was a forcible and clear speaker in the debates of his chosen societies, and he had a quick intuition as against measures and methods that

opposed the progress and honor of the profession, but of late years he has been little known in the medico-literary world. Fifty years ago he was prominent in a committee on library in the State Medical Society, and some of the results of his committee's labors rest among the 10,000 medical volumes on the shelves of the Public Library of Boston. Within the past two years, however, his friends and former students have made it possible for the Medical Library Association of that city to place upon its walls an exceptionally fine portrait of this lover of books, of natural science and of the healing art. When he was seventy-nine years old he was troubled with vesical calculus, and was operated upon successfully by the late Dr. H. J. Bigelow. His retirement from professional activity had been gradually progressing before that operation, but after that it became more decisive. This retirement, however, left him with a mind well furnished for life's decline, and he sustained his long time reputation for cordiality and geniality and a lively sympathy with the junior members of the profession. The date of his death was September 10.

BOOK REVIEWS.

REGIONAL ANATOMY IN ITS RELATION TO MEDICINE AND SURGERY. Illustrated from photographs taken by the author of his own dissections, expressly designed and prepared for this work, and colored by him, after Nature. By GEORGE MCCLELLAN, M.D. Vol. I. Imp. 4to. Pp. 431. Philadelphia: J. B. Lippincott & Co., 1891.

As the title indicates, the book is original in its design and execution. This work covers not only the matter usually comprised in ordinary works on surgical anatomy, but as well the surface anatomy, or "land-marks." Surface anatomy is not only a necessary study for the artist, but for the surgeon, especially in these days of the phylotomists, when every swelling must be "explored," and the unfortunate abdomen slashed open whenever there is any unusual change in its contour. The more knowledge of surface anatomy, the less "exploratory" slashing. The more knowledge of surface anatomy, the more accurate the diagnoses in injuries of the joints, and the fewer the litigants in malpractice suits. Prof. McClellan, himself a teacher of anatomy in the Pennsylvania Academy of Fine Arts, as well as in a medical school, has given the most complete exposition of the subject.

The illustrations are accurate and handsomely executed, the coloring is natural, and the book is one of which all American medical men may well be proud, and the author has in this work added new laurels to a line already distinguished in the annals of American medical literature.

The publishers have done their part well; the paper is good, the typography excellent, and the whole make-up is highly creditable to the house.

There are many books which the general practitioner and surgeon can better afford to spare than this one.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
NO. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, OCTOBER 3, 1891.

CREATIN IN TUBERCULOSIS.

In a report to *The Times and Register*, Sept. 26, 1891, Prof. SAMUEL G. DIXON, of Philadelphia, gives the results obtained by injections of creatin in tuberculous animals. His own experiments were made on tuberculous and healthy rabbits and guinea-pigs, the results being as satisfactory as could be expected with these particular animals. At his request, W. L. ZUILL, M.D., Professor of Veterinary Surgery in the University of Pennsylvania, made experiments on healthy and tuberculous cows. Prof. ZUILL reports as follows:

TO PROFESSOR SAMUEL G. DIXON, M.D.:

Dear Doctor:—I hereby submit to you the clinical results obtained from the subcutaneous injection of creatin in tuberculous cattle. The experiments were made in accordance with our pre-arranged plan, and have extended over the last two months. The results obtained in these experiments more than fulfill my utmost expectations, and are in every respect identical with those which I have obtained with tuberculin. The physiological action of creatin in tuberculous cows is so exact and identical with tuberculin that it is impossible to recognize a clinical difference. Its influence upon circulation and respiration is well marked in animals suffering with miliary tuberculosis of the lungs, but large doses of the drug do not react upon these organs should the disease be confined to the other tissues of the body.

The action of creatin upon tuberculous tissues is intensely energetic, causing rapid necrosis of this tissue, giving it the appearance of having undergone a cystic degeneration. The cheesy degeneration of tuberculous tissue seemingly disappears, and its place is taken by necrotic cavities filled with serum, in which float threads and masses of the tuberculous structure more or less large.

August 13.—Experiment No. 1 was made with one-twentieth of a grain of creatin in a tuberculous cow, with no well-marked reaction.

August 27.—Experiment No. 2 was made with one-sixth of a grain of creatin in a tuberculous cow, which caused an elevation of temperature from one hundred and one to one hundred and four and one-fifth degrees F.

September 9.—Experiment No. 3 was made with one-half of a grain of creatin in a tuberculous cow, and caused an elevation of temperature from one hundred and one and one-fifth degrees to one hundred and three and four-fifths degrees F.

September 21.—Experiment No. 4 was made with 1 gr. of creatin in a tuberculous cow, and caused a reaction in temperature from one hundred and two and one-fifth degrees to one hundred and five and three-fifths degrees F.

September 4.—Check experiment No. 2 was made with $\frac{1}{16}$ of a gr. of creatin in a healthy cow, and no reaction could be observed.

September 9.—Check experiment No. 3 was made with $\frac{1}{2}$ of a gr. of creatin in a healthy cow, and no reaction could be observed.

September 24.—Check experiment No. 4 was made with 1 gr. of creatin in a healthy cow, and no reaction could be observed. Respectfully,
W. L. ZUILL.

It is to be borne in mind that the normal temperature of the cow is from 101° to $102\frac{1}{2}^{\circ}$ F.

Prof. DIXON has on hand a series of experiments with other members of the amide group, viz.: allantoin, glycosin, tyrosin, creatinin, taurin, cystin, etc.

WE CONGRATULATE the readers of THE JOURNAL upon the large amount of valuable original matter presented this week. In addition to the usual amount of Section work of the Association, our readers have before them a very full abstract of the proceedings of the general session of the Congress of American Physicians and Surgeons, held last week in Washington, as well as a partial report of the proceedings of the American Surgical Association.

THE DOCTORS OF NORTHERN OHIO will gather at Mansfield, November 5-7, for at that time and place, the three Societies of Northern Ohio, viz.: the Northwestern Ohio Medical Society, the North Central Ohio Medical Society, and the Northeastern Ohio Medical Society, hold a union meeting.

On the evening of November 5, the Hon. John Sherman will give a reception in honor of the Association, and the next evening the Hon. M. D. Harter will give a reception. The Committee of Arrangements consists of Drs. R. Harvey Reed, J. W. Craig and Geo. Mitchell, all of Mansfield.

DR. FRANK W. REILLY, of Chicago, has been appointed Secretary of the State Board of Health

of Illinois, vice Dr. John H. Rauch, resigned. In accepting the resignation of Dr. Ranch the Board passed complimentary resolutions, warmly eulogizing him, which are this week crowded out on account of the great pressure upon our columns.

His successor, Dr. Reilly, was for many years a surgeon in the Marine-Hospital Service, and afterwards a well-known writer for the daily press. He was Dr. Rauch's assistant for some months, and for the last four years has been the managing editor of the *Chicago Daily News*.

Bringing a trained pen to the service of the Board, his success as Secretary is well assured.

MISCELLANY.

ILLINOIS ARMY AND NAVY MEDICAL ASSOCIATION.—The Illinois Army and Navy Medical Association was organized at Springfield, Ill., June 26, 1890, with Dr. Hosmer A. Johnson, of Chicago, as President, and Dr. John H. Rauch as Secretary. The objects of the Society are, the promotion of social intercourse, and historical and medical subjects connected with the late War. All reputable physicians now living in Illinois, whether in practice or not, who served in the Army or Navy during the late War, and all who were Surgeons, or Acting Asst. Surgeons, who were with Illinois troops, and are now non-residents of the State, are eligible to membership. At the second meeting of the Association, held in Springfield, May 18 and 19, 1891, Dr. John H. Rauch was elected President, vice Dr. Johnson, deceased, and Dr. Edward P. Bartlett, of Springfield, was elected Secretary. The Association adjourned to meet in Chicago, at the time of the unveiling of the Grant Monument. This adjourned meeting will take place at the Grand Pacific Hotel, October 7 and 8, 1891. All physicians who served in the Army or Navy, during the late War, are cordially invited to meet with us. The unveiling of the monument will take place October 7, at 2 P.M.

Reduced rates are promised by the railroads.

EDWARD P. BARTLETT, Sec'y.

AMERICAN MEDICAL ASSOCIATION—SECTION ON SURGERY.—The Chairman of the Section requests members who expect to present papers in this Section to forward the titles of their contributions as soon as possible to the secretary of the Section, F. W. MANN, M.D., Detroit, Mich. The programme is being rapidly filled, and it is the desire of the officers to make it thoroughly representative in all departments of surgical work.

MITCHELL DISTRICT MEDICAL SOCIETY.—The semi-annual meeting of the Mitchell District Medical Society will be held at Columbus, Ind., Thursday and Friday, December 17 and 18, 1891. Physicians desiring to read papers at this meeting will please forward the titles of

their papers immediately. This promises to be one of the best meetings ever held by this well-known medical Society.

GEO. T. MCCOY, M.D.,
Chairman Com. of Arrangements.

ANNALES D'OCULISTIQUE.—This long-established and widely known ophthalmological journal, conducted during many years with distinguished ability by the late Professor Warlomont, has, since the death of that illustrious leader in ophthalmology, passed into the editorial hands of Drs. Valude and Sulzer, who have transferred the office of publication from Brussels to Paris.

The new management has doubled the size of the journal and promises to increase its usefulness.

Dr. George T. Stevens, of New York, the American collaborator, will report matters of ophthalmological interest from this country.

Those who are familiar with *Annales d'Oculistique* will have already observed a very marked change in the prominence given to American literature in the last two numbers.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from September 19, 1891, to September 25, 1891.

Asst. Surgeon Theodore F. DeWitt, U. S. A., granted leave of absence for six months, on surgeon's certificate of disability.
Asst. Surgeon Jefferson R. Kean, U. S. A., granted leave of absence for three months, on surgeon's certificate of disability.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending September 26, 1891.

P. A. Surgeon E. H. Marsteller, detached from U. S. S. "Petrel," and granted one month's leave.
P. A. Surgeon O. D. Norton, detached from special duty at Naval Academy, and to the U. S. S. "Petrel."
Surgeon J. H. Hall, detached from Naval Hospital, Chelsea, Mass., and placed on waiting orders.
Surgeon G. P. Bradley, ordered to Naval Hospital, Chelsea, Mass.
Surgeon C. U. Gravit, ordered to Naval Hospital, Brooklyn, N. Y.
P. A. Surgeon J. F. Gardner, detached from Naval Hospital, New York, and to the Naval station, New London, Conn.
Asst. Surgeon J. H. North, detached from Navy Yard, New York, and wait orders.
Asst. Surgeon Geo. A. Lung, detached from Naval Station, New London, Conn., and to the Navy Yard, New York.
Surgeon M. H. Simons, detached from the "Enterprise," and to hold himself in readiness for sea service.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Six Weeks Ending September 19, 1891.

Surgeon George Purviance, granted leave of absence for thirty days. August 22, 1891.
Surgeon W. H. Long, granted leave of absence for twenty-two days. August 18, 1891.
Surgeon H. W. Austin, to proceed to Delaware Breakwater Quarantine Station as Inspector. August 28, 1891. Granted leave of absence for thirty days. September 3, 1891.
Surgeon J. M. Gassaway, granted leave of absence for ten days. September 19, 1891.
Surgeon G. W. Stoner, granted leave of absence for ten days. August 15, 1891.
P. A. Surgeon H. R. Carter, to proceed to Cape Charles Quarantine for temporary duty. August 27, 1891.
P. A. Surgeon W. A. Wheeler, to proceed to Cape Charles Quarantine for temporary duty. August 27, 1891.
P. A. Surgeon C. E. Banks, granted leave of absence for eleven days. September 3 and 9, 1891.
P. A. Surgeon D. A. Carmichael, leave of absence extended thirty days on account of sickness. September 10, 1891.
P. A. Surgeon A. H. Glennan, granted leave of absence for seven days. August 29, 1891.
Asst. Surgeon G. M. Guiteras, relieved from duty at San Francisco, Cal.; to proceed to New Orleans, La., for special duty. September 14, 1891.
P. A. Surgeon C. P. Wertenbaker, granted leave of absence for thirty days. September 10, 1891.
Asst. Surgeon J. C. Perry, to proceed to Evansville, Ind., for temporary duty. September 18, 1891.
Asst. Surgeon G. B. Young, granted leave of absence for eight days. August 29, 1891. To proceed to Cairo, Ill., for temporary duty. September 15, 1891.
Asst. Surgeon E. R. Houghton, to proceed to Vineyard Haven, Mass., for temporary duty. August 29, 1891. Granted leave of absence for sixty days, and permission to go abroad. September 18, 1891.

PROMOTION.

Asst. Surgeon H. T. Goodwin, commissioned as P. A. Surgeon, to date from September 24, 1891. September 18, 1891.

THE TREATMENT OF HYPERTROPHIED TONSILS.

*Read by title before the Section of Laryngology and Otology, at the
Forty-second Annual Meeting of the American Medical
Association, Washington, D. C., May 1, 1891.*

BY CHAS. H. KNIGHT, M.D.,

OF NEW YORK.

PROFESSOR OF LARYNGOLOGY AND RHINOLOGY, NEW YORK POST-
GRADUATE MEDICAL SCHOOL; SURGEON MANHATTAN
EYE AND EAR HOSPITAL.

An enlarged tonsil may project beyond the pillars of the fauces without giving rise to any special subjective symptoms, or it may provoke serious disturbance and yet be invisible except during the act of retching. It may interfere with hearing, impede breathing, or obstruct swallowing, or it may simply be the cause of pharyngeal irritability or of various reflex disorders. The amount of functional derangement excited by an enlarged tonsil depends in part upon the relative dimensions of the faucial space and upon the temperament of the individual. Moderate hypertrophy in a contracted pharynx or in a neurotic subject may be the source of excessive annoyance, whereas an extreme degree of enlargement may be easily tolerated in a capacious pharynx or by a phlegmatic subject.

At the present day but few will be found to object to the statement that hypertrophied tonsils require to be reduced or removed, even in the absence of marked subjective symptoms. For whatever function these organs were intended it must be admitted that in their hypertrophied state they have become incapable of performing it, and are therefore useless appendages. Moreover, there is abundant clinical evidence to show that their presence invites contagion, and in the event of infection they become a serious complication.

For example, during an epidemic of diphtheria children with large tonsils are more prone to contract the disease and are apt to have it in a severe form. The old fallacy, as maintained by Ottenbourg,¹ that enlarged tonsils are a protection against croup, must give way to the modern and more scientific opinion that, even without having undergone marked increase in size, the tonsils

may become avenues for the admission of disease to the system, in consequence of a condition described by Zawarykin² as "rarefaction of the epithelium." Its pathological importance has recently been verified by Hodenpyl,³ who expresses the belief that "it has an important bearing upon the absorption of bacteria and their ptomaines and in the production of certain of the acute infectious diseases." Admitting, therefore, that diseased tonsils should not be ignored as of trifling consequence, we must answer the question as to the best method of treatment. So many elements are concerned that we may safely affirm that no one method is adapted to all cases. Those who cut every tonsil and look upon other methods as puerile and unsurgical, must often find their attempts at excision to some extent foiled by certain anatomical peculiarities, or by strenuous objection on the part of the patient. On the other hand, those who advocate the invariable use of cauterization not infrequently accomplish by painful and tedious methods what might be done in a few moments with equal safety.

The treatment of enlarged tonsils may be divided into medical and surgical. The former may be dismissed in a few words, since clinical experience shows that the hypertrophied tonsil yields slowly if at all to internal medication, except, perhaps, in struma or anæmia. In such cases hygiene, diet and tonics may have a limited influence. The same is true of local applications resorted to for the purpose of promoting absorption. In the majority of cases whatever constitutional defects may be present are directly attributable to the tonsillar hypertrophy, and are best remedied by removing the latter. Without wasting time in futile efforts to amend the systemic condition we should resort at once to surgical measures.

The following enumeration includes most of the methods which have been or continue to be practiced. Some of them have long since been abandoned, while others have never found favor except in the hands of their promoters:

1. Electrolysis.
2. Massage.
3. Chemical caustics.
4. Galvano-cautery puncture, or ignipuncture.

5. Avulsion with forceps.
6. Ligation.
7. Enucleation by means of the finger.
8. The cold wire snare.
9. The galvano-cautery snare, or amygdalotome.
10. Excision by means of scissors, the bistoury, or the guillotine.

1. Electrolysis: Interest in this method is not altogether lost, since we find within the past month a contribution to the technique of electrolysis in enlarged tonsils. A bifurcated needle electrode has been devised by Dr. Henry L. Coit,⁴ and is said to facilitate the operation. The needle, which is inserted into the tonsil, carries the negative current, while the positive electrode is applied externally. The applications are made weekly, are painless and bloodless, and are supposed to promote "absorption of the fibrous exudation, without destroying the mucous membrane," whatever that advantage may be. At a recent meeting of the American Laryngological Association, during the discussion of a paper on the galvano-cautery in hypertrophied tonsils, Dr. T. A. DeBlois⁵ stated that he had obtained good results with electrolysis, making half a dozen punctures each day. He uses it only in adults. Cohen⁶ also mentions having used it successfully in certain cases, while in others the results were not worth the trouble. At best it appears to be very slow, and it would seem to be fair to question whether the other measures generally used in conjunction with the electrolytic treatment are not at least equally responsible for whatever slight shrinkage may be observed.

2. Massage is referred to by many writers, but it evidently has not been extensively used. Good results have been reported by Quinert,⁷ who recommends rubbing powdered alum into the tonsil.

3. Almost all the agents in the list of chemical caustics have been at various times employed to destroy enlarged tonsils. Not more than three have proved of permanent value, namely: nitrate of silver (Holmes),⁸ chromic acid (Donaldson),⁹ and London paste (Mackenzie).¹⁰ The first is most effective when passed into the lacunæ of the tonsil, the second is used after making small incisions, and the third is applied to the surface of the tonsil with a spatula. Several objections are common to all. Their action is slow and in some cases is limited with difficulty, so that they can be safely used only when we have the coöperation of our patient.

4. The foregoing objection applies with less force to galvano-cautery puncture and ignipuncture. The application of these agents is much more precise, the immediate pain and the inflammatory reaction are certainly no more than with chemical caustics. In a tolerant patient much more rapid work may be done, nearly the whole tonsil sometimes being destroyed at a single sit-

ting. In spite of the testimony of many recent writers (Saint Germain), I have not found that children submit quietly to this method of treatment, and even in adults, and with the free use of cocaine, a good deal of complaint is made. In my judgment galvano-cautery puncture is undoubtedly the best resource in those broad, flat, adherent and deeply embedded tonsils, which cannot be reached at all with the guillotine, and whose removal with the knife is more or less difficult and hazardous. Krishaber,¹¹ who is one of the most ardent advocates of ignipuncture, sums up his views as follows: It is not painful. It is attended by no complications and results are prompt. Its application is easy, and its use, except in rare cases, demands no extraordinary skill.

5 and 6. Avulsion with forceps and ligation are of historical rather than of present practical interest. The former seems to have been practiced in very early times, while the latter has been more recently advocated by Guillemeau and Moscati. In referring to the latter Krishaber remarks that it is dangerous because of the inflammatory reaction likely to ensue.

7. Enucleation by means of the finger was practiced by Celsus and it has been since his time occasionally used, probably more from curiosity than because it has anything to commend it. It seems to be easily performed, except when the attachments of the gland are unusually firm and dense. The contusion of the parts necessitated by removing a tonsil in this way would be likely to induce an excessive degree of soreness. (Bernardino,¹² Larghi,¹³ Borelli,¹⁴ Farmer.)¹⁵

8. With the cold wire snare (Jarvis)¹⁶ primary hæmorrhage should not occur, provided the section be not too rapid, but there is always, of course, a possibility of secondary bleeding unless the usual precautions as to diet, movements of deglutition, clearing the throat, etc., are observed. In the few cases in which I have used it the process has been extremely painful, the tightening of the loop, as it gradually contracted upon the tissues at the base of the tonsil, became more and more difficult, and the subsequent distress of the patient was certainly excessive.

9. In the adult, in whom we may have cause to expect hæmorrhage, or who refuses to be cut, the galvano-cautery snare or Dr. Jonathan Wright's¹⁷ ingenious adaptation of the electric current to the frame of the Mackenzie guillotine, will be found serviceable. Some dexterity is doubtless required for the successful manipulation of the snare, which is not the case with the electric amygdalotome. The latter is used precisely as if it were a cutting instrument. The most satisfaction will be found with these methods in protuberant tonsils from which the palatal folds are quite free.

10. In the large majority of cases excision is the operation of choice. In tractable cases the

knife may be used with safety, but it is difficult to see that it has any advantage over the guillotine. The latter, if properly handled, will give an equally good result, and is undoubtedly safer. Scissors are perhaps less dangerous than the knife, but must be more awkward to handle. Cohen seems to be almost the only authority who sees greater danger to the palatine folds in the guillotine than in the bistoury. The only cases of fatal hæmorrhage and, with but few exceptions, the only cases of alarming hæmorrhage have occurred after the use of the bistoury.

Leaving out of the question the condition of hæmatophilia, in which a cutting operation is of course contraindicated, we find four possible sources of hæmorrhage after excision of the tonsils: 1. Wound of an anomalous ascending pharyngeal artery. 2. Injury of an abnormally vascular pillar. 3. Section of the venous plexis sometimes found at the lower border of the tonsil. 4. An enlarged and patulous artery in the body of the tonsil itself. The first two may exist at any age, but are likely to be met with only when the bistoury is used rather than the guillotine. The third occurs only in adults, and the fourth is certainly not common before puberty. My own conviction is that the danger of hæmorrhage from any source has been grossly exaggerated, largely perhaps in consequence of the unfortunate fact that many of those in the habit of excising tonsils are not schooled in general surgery and are hence easily alarmed by the sight of blood.

In my experience it is not the vascular looking tonsil that bleeds. From such a tonsil the flow of blood may be at first profuse, but it is soon checked by the ready retraction of the blood vessels. It is the pale, fibrous tonsil of the adult and of advanced childhood which gives us trouble. And the explanation is obvious. A tonsil of this kind is characterized by large increase of its connective tissue, by which the blood vessels are held open. A clot forms with difficulty and possibly only on the approach of syncope, as the pressure from behind diminishes. The foregoing statement suggests a point as to the amount of tonsil to be removed. It has repeatedly been said that it is merely necessary to remove the projecting portion, with the expectation that the remnant will ultimately shrink. It is curious to notice the difference of opinion expressed by various authorities on this subject. In his monograph on hypertrophied tonsils Paul Balme¹ especially insists upon the importance of avoiding excessive outward pressure with the tonsillotome lest the pillar of the fauces be wounded and hæmorrhage follow. Amygdalotomy and not amygdalectomy, partial rather than complete excision is advised. Deroubaix¹⁹ claims that but little more than the projecting portion need be removed. Seiler²⁰ says that "total ex-

tirpation or enucleation is also dangerous besides being unnecessary, except in the extremely rare cases of cancerous growth in the tonsils." Prosser James²¹ remarks that a small portion sliced off is an effectual remedy, as the remainder of the tonsil shrinks within the pillar and the cure is complete! Philip Schech²² claims that removal of the whole tonsil is unnecessary and dangerous; only the projecting part should be removed. Yet he admits the danger of wounding the carotid does not exist if the tonsillotome be used. Sir Morell Mackenzie²³ advocates partial removal, and Cohen²⁴ says that excision of the entire gland is "hardly ever requisite." He prefers the knife in adults, the amygdalotome in children. On the other hand, Lennox Browne²⁵ always endeavors to remove "as much of the gland as can be pressed into the guillotine," and does not look for atrophy of the rest. Bosworth²⁶ asserts that the "whole organ should be removed if possible in all cases." Examination of a large number of cases supports the belief that the stump of an excised tonsil does not, as a rule, shrink to an appreciable degree, but on the contrary remains as a source of irritation and is prone to recurrences of inflammation. In the second place, it is almost impossible to wound the pillar with a properly constructed guillotine, and, if that accident should happen, hæmorrhage, except under most extraordinary circumstances, could not be serious. Finally, and this is a point of no little moment, as much of the tonsil as possible should be removed, for the reason that deep section of the blood vessels through normal tissue permits them to contract so that spontaneous control of hæmorrhage is much more likely to occur. We can therefore accomplish a satisfactory excision of a tonsil only by strong outward pressure with the tonsillotome against firm support from without furnished by the hand of an assistant. As Mackenzie has remarked, this operation is almost the only one in our department requiring the exercise of brute force. There are two reasons, therefore, for making the extirpation of the tonsil as radical as possible: 1. Tendency to recrudescence is lessened; and 2, danger of hæmorrhage is diminished.

In conclusion, there are two points in connection with this subject which seem to me worthy of attention. One relates to the selection of an instrument, and the other to the use of anæsthesia. There seems to me no question that Mackenzie's modification of Physick's well-known guillotine is incomparably superior to all other instruments. Such accidents as have been reported by Schuler²⁷ and Barré²⁸ with the Mathieu tonsillotome could hardly happen with the Mackenzie instrument. The addition of a fork to the guillotine not only complicates the operation but adds to the difficulty of keeping the instrument aseptic. If properly managed the Mackenzie

tonsillotome will cut only the tonsil and in suitable cases it will remove as much of the organ as may be desired. This instrument commends itself, therefore, because of its strength, its simplicity, its safety, and its effectiveness.

There no doubt exists some prejudice against the use of an anæsthetic in removing tonsils. In the course of a discussion at the Paris Surgical Society, Reclus²⁹ referred to an unpublished case of fatal asphyxia during a tonsillotomy under chloroform. Avoid profound anæsthesia, remove the tonsils in quick succession, immediately turn the patient upon the face, and such a misadventure cannot occur. Some years ago Ingals³⁰ remarked that removal of the tonsils is as serious a matter for a child as it would be for an adult to be hung. In young children, therefore, we should use ether or chloroform, not only to obviate mental and physical suffering, but, what is much more important, in order to enable us to explore the naso-pharynx at leisure, and if necessary to remove from that region those collections of lymphoid hypertrophy so often associated with similar overgrowths between the palatine folds.

20 W. 31st street.

LOCAL ANÆSTHESIA WITH THE PHARYNGEAL COCAINE SYRINGE.

Read by Title in the Section of Laryngology and Otology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY JNO. E. BOYLAN, M.D.,
OF CINCINNATI.

Mr. Chairman and Gentlemen:—I had occasion to report last year, at Nashville, a method of effectually anæsthetizing the tissue of the vault of the pharynx before operating upon adenoid vegetations, by the interstitial injection of cocaine with a suitably constructed and guarded needle syringe.

I wish to-day to make a brief report of observations with the instrument during the past year, and as it was incomplete when exhibited, and has since been somewhat modified, I take the liberty of producing it again. An objection raised to the use of the instrument, which was otherwise kindly criticized at the time, was the danger of calling forth alarming or even fatal symptoms by subcutaneous injections of cocaine.

Dangerous and disastrous results from the use of cocaine as a local anæsthetic was, from the start, the bugbear that stalked at the heels of this brilliant and most happy innovation, as it was upon the introduction of the general anæsthetics, chloroform and ether; and yet I should like to ask how many of the gentlemen present have found this objection a sufficiently grave one to have prompted them to desist from its use? Though we occasionally hear the note of warning, and here and there a fatal case has been reported, their proportion has not increased with the prevalence of the drug, while its use has become so universal, among the specialists particularly, that it is to be doubted if there are many of the latter who could now be induced to do without it. With the report of fatal cases we are almost invariably informed of the size of the dose administered, and I have yet to hear of a single one which was not much larger than necessary to produce satisfactory local anæsthesia.

Aside from the repeated applications to the mucous membrane of the nose and throat, made almost daily over a period of about four years, I have, since May last, injected cocaine into the tissue at the vault of the pharynx of thirty-seven different patients. I have never failed to make a note of cases in which symptoms other than local anæsthesia were manifested, and of these there are nine all told. In five of the nine cases, toxic or constitutional symptoms, such as hilarity, pallor, somewhat labored respiration or tendency to syncope, occurred after the application of about 30 m. of a 20 per cent. solution with a brush. The remaining four cases occurred after hypodermic injection, and as follows: The first three happened among the first ten cases treated, and following an injection of 20 m. of a 10 per cent. solution, or about 2 m. of cocaine, while the fourth was the only one which occurred among the last twenty-seven cases, after reducing the injections to 15 m. of the same solution, to which quantity they have since been confined. In only one of all the cases were the symptoms at all alarming. In this instance the patient was a robust boy 15 years of age, and the dose, which was injected with the syringe, was possibly a little more than 20 m. Within two minutes the patient became pale, and stated that he was growing numb and dizzy. He stamped about for a few minutes, slapping his hands and legs, which seemed to be rigid with cramp; his respiration

became labored, the dizziness increased, and he insisted upon lying down to sleep. Some whisky, a current of fresh air from the open window, and friction, gradually rallied him from this condition, and within twenty to thirty minutes he was completely restored. A week later, an injection of exactly 15 m. into the same patient was followed by but slight pallor and somewhat accelerated respiration, which did not impede the operation.

As the result of the above, as yet, rather limited observations, I infer that the amount injected should be about one-half that which may be applied to the mucous membrane. I believe m. 15 of a 20 per cent. solution a perfectly safe quantity to inject, and I have never known such a dose to fail in producing within five minutes entirely satisfactory anæsthesia, so that the patient never complained of pain from the operation.

The chief points of advantage which may be claimed for this method of anæsthetization are, 1, that it greatly reduces the percentage of cases in which a general anæsthetic must be resorted to, by effectually benumbing the part; 2, the ease and celerity with which it is accomplished, for it is done in an instant, and regardless of the ordinary retraction of the palate, the guarded point being quickly inserted between the latter and the pharyngeal wall, if necessary; 3, the rapidity and completeness of its effect; and 4, the fact that no cocaine is swallowed or retained in the nose, which does not assist in producing anæsthesia in the pharynx. As obstructions of the lumen of the needle necessitated various trips to the instrument makers, this has been made to screw to the canula, and can easily be detached with a forceps and cleaned. The instrument is made by Tiemann & Co., of New York, and by Max Woche & Co., of Cincinnati.

AN ABSTRACT OF PAPER ON CHRONIC CATARRHAL LARYNGITIS.

Read by Title in the Section of Laryngology and Otology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY MARION THRASHER, M.D.,
OF SAN FRANCISCO, CAL.

Chronic catarrhal laryngitis is a continuous passive inflammation of the laryngeal mucous membrane. Its etiology is multifarious. The most influential causes are nasal stenosis, liquor drinking, tobacco smoking, vitiated air, and an intemperate use of the vocal organs.

Nasal stenosis necessitates mouth breathing—an abnormal respiration, by which we have carried into the laryngeal cavity an air pregnant with dust, that soon begets an inflammatory process.

Chronic alcoholism produces an abnormal activity of the mucous glands of the mouth and

fauces, which, during sleep, drops depraved excretions into the larynx, thereby producing a permanent inflammation.

Tobacco smoking causes to be deposited daily in the air passages the liquid alkaloid nicotine, which produces partial paralysis of the vaso-motor nerves of this locality, and a resultant permanent injury to the mucous texture.

Vitiated air, in illy ventilated apartments, is one of the commonest causes of chronic laryngitis. Air reeking with noxious vapors poisons the delicate tissues over which it passes, fails in its mission of aerating the blood, and by its toxic reaction, superinduces a chronic hyperæmia of the respiratory tubes.

An intemperate use of the vocal organs in criers, speakers and singers, must of necessity produce chronic laryngitis. Mandl says, in singers and orators, the arytenoids and vocal cords are inflamed, while in drinkers and smokers, the inflammation exists in the epiglottis and aryglottic folds.

The pathological condition is always one of hypertrophy of the mucous membrane of the larynx. This is a diagnostic symptom, and is accompanied by all or part of the following symptoms: difficult nasal respiration, morning hoarseness, decreasing with the day, cough, dysphagia, copious secretion and excretion, supplemented always by a feeling of uneasiness or discomfort—but by an absence of positive pain.

The prognosis of chronic laryngitis is favorable as to fatality, but usually unfavorable as to a permanent cure. For years, extending to a long lifetime, it may continue, with remissions and exacerbations, and not perceptibly affecting the general health. The difficulty in the way of a permanent cure, lies in a failure in keeping up a given line of treatment for a sufficient length of time. Both physician and patient may at first be enthusiastic, but as days, weeks and months go by, the enthusiasm wanes, the treatment is neglected or wholly ignored—or perchance a temporary abatement of the prominent symptoms had led them into the belief that a cure had been accomplished. We should not forget to impress upon the mind of the patient and his friends, that a chronic disease can only be successfully combated by chronic treatment.

The pathological factor is hyperæmia. The chronic inflammation of the laryngeal membrane has produced a permanent distension of the capillaries—oversecretion and supersensitiveness.

The treatment may be local, general, or both—guided by the etiology. No less an authority than Lennox Browne claims but little for constitutional treatment. The experience of most physicians will not agree with his. The treatment may properly be local, constitutional, or both. The exciting cause must be discovered and overcome. The diagnosis can readily be made with

the laryngeal mirror. If the etiology points to portal congestion, chloral hydrate would be indicated; if a syphilitic taint, mercury; if tuberculosis, iron and cod-liver oil; if glandular enlargement, one of the iodides. The necessity of constantly breathing pure air cannot be too strongly dwelt upon. Let the diet be light, digestible and nutritious. The plethora of glutony should be guarded against. For the treatment of chronic laryngitis, I know of no one remedy so efficient as alcohol. Unlike many others, it is applicable in all cases, irrespective of cause. It is a local and constitutional tonic, acting not only beneficially on the lining membrane of the air passages, but also as a systemic stimulant.

Nasal stenosis is reduced, and as a rule permanently cured, by alcoholic inhalation. Pharyngitis is relieved, and the uvula—usually elongated in laryngitis—is rendered normal. Several cases of tuberculosis, well advanced, have been checked, in my practice, by alcoholic inspiration. Wearing a full beard among men, has been strongly recommended by some medical writers as a remedy, both curative and preventive, for chronic laryngitis.

A thermometrical sameness, secured either by latitude, altitude or artificial methods, must not be overlooked, as one of the most potential of the remedial agents—but by all means, let your treatment be measured by months rather than days.

THE GALVANO-CAUTERY IN LARYNGOLOGY, WITH CASES.

BY GEO. W. WEBSTER, M.D.,

OF CHICAGO, ILL.
PROFESSOR OF PHYSIOLOGY CHICAGO MEDICAL COLLEGE.

The object of this paper is to produce evidence tending to show that the galvano-cautery, and especially the snare, is a decided addition to the armamentarium of the laryngologist, and the method entitled to legitimate recognition. As a rule it is condemned most loudly by those who have used it the least, basing objections on theoretical grounds, and in most instances the objections urged are, it seems to me, not well sustained by the facts, nor by personal experience.

The variety of cases in which I have used the cautery in laryngology with advantage, are hypertrophy of the tonsils, cancer of the œsophagus with growth protruding into the larynx, papilloma of the larynx and abscess of the larynx.

In regard to the cautery in removal of the tonsils, I have used this method for three years, and *no other method* for two years. In using the galvano-cautery it is of prime importance that we have a handle so made as to allow the operator to make or break the current at will, and to at the same time operate the windlass with the

thumb. The Flemming handle, or some of its modifications, is the instrument preferred by the writer. It is equally important to have a current that will heat the wire quickly and at the same time be controlled by a rheostat. Platinum wire is the only material that can possibly give satisfaction; and some form of storage battery will be found most serviceable.

In removal of the tonsils it seems to possess the following advantages:

1. Consent of the patient, as there is neither cutting nor hæmorrhage.
2. Absolutely no primary hæmorrhage, although the probability of secondary hæmorrhage is probably not lessened.
3. Greater facility of application, especially in small hypertrophies, and in many children with small throats, where an instrument of larger size could not be easily applied.
4. Better results because of lessened tendency to return, and less absorption after the operation.
5. In large hard hypertrophies where hæmorrhage is feared and where the cold snare is recommended by some writers.

Some form of tonsil forceps is always needed to aid in raising the tonsil from its bed. The forceps of Fanenger and of Ingals I have found the most convenient and valuable.

In using this method in public and in private practice in about one hundred and fifty cases I have had no unpleasant results, and only one case of slight secondary hæmorrhage.

In the removal of growths from the larynx the cautery has the following advantages:

1. Perfect safety, as the current is *never* turned on until the growth has been firmly grasped by the loop.
2. A small instrument which when in the larynx allows one to obtain a more perfect view of the parts, thus facilitating greater accuracy.
3. Absolutely no hæmorrhage, thus allowing growths to be removed piecemeal at one sitting, which could not be done by any other method where hæmorrhage obscures vision.
4. In papilloma of the larynx where the base is thus cauterized there is, I believe, less liability to recurrence.

I would not be understood as advocating this method to the exclusion of others, nor as even intimating that it is applicable to all cases, but where any growth can be grasped by the loop I believe it to be the best method.

Case 1.—Miss O., 26 years of age, saleslady by occupation, general health good, consulted me three years ago for laryngitis. At that time there was an acute inflammation and the membrane in the inter-arytenoid space was thickened and showing some rugæ when patient phonated.

Consulted me again May 25, 1891. At this time the patient could only whisper and she in-

formed me that she had not been able to speak aloud for several weeks, and that for over a year she had been always hoarse and much of the time completely aphonic, and that she is growing constantly worse notwithstanding almost constant treatment by various physicians. She says there is no pain in or about the throat, but complains of a tired feeling after attempted speaking. There was no swelling of the glands on the outside of the neck.

Family history reveals the fact that one sister died of pulmonary tuberculosis. Patient is large, strong, well nourished and has normal temperature.

Laryngoscope examination shows a general subacute laryngitis, and also reveals a rough, irregular growth of a slightly opalescent color apparently very nodular and occupying the interarytenoid space, and being separated into two lobes by a perpendicular fissure. It was almost a half inch in length from above downward and smaller in a transverse direction, and by its size and location mechanically prevented the approximation of the vocal cords by contraction of the arytenoid muscle, thus rendering phonation impossible. I informed the patient that I had never seen such a growth in that location, but supposed it was papilloma, but that a positive diagnosis could be made only by a microscopical examination, or noting whether the growth recurred, and advised removal. This was consented to and the galvano-cautery was the method chosen.

After a thorough application of cocaine (10 per cent. solution) I passed the loop into the larynx and after a few moments of patient manœuvering I succeeded in getting the loop firmly around it, and it was quickly removed without pain or hæmorrhage. On inspection I was not quite satisfied with the appearance of the base, so I then introduced another form of electrode and cauterized more completely the surface from which the growth had been removed. After the operation was completed the patient could speak aloud but was somewhat hoarse.

Unfortunately, just as I was removing the loop from the mouth the growth became detached and fell into a jar containing some blood, several quarts of water and masses of adenoid vegetation just removed, and I was therefore unable to secure and examine the specimen.

The treatment after the operation consisted in rest of the voice for one week. Morphæ gr. one-eighth the first night. Locally, iodoform in glycerine 10 per cent. applied once each day with cotton on applicator.

There was a little increase in inflammation on the day of the operation, but on the second day the inflammation had decreased and from that time on the improvement was rapid and the patient began work as saleslady at the end of the

week, although I objected to her doing so. The second week I applied each day a spray of silver nitrate, 15 gr. to the ounce; the third week the same solution every second day.

The inflammation has now quite disappeared, the voice is as good as ever in her life and she is able to sing fairly well and that for the first time in nearly four years. Of course it is too early in the case to make a diagnosis, for it may have been tuberculous papilloma; but no one will deny, although all do not appreciate fully the value of radical treatment in these cases, and this is especially true if they are tubercular.

Case 2.—Mr. X., laborer, about 28 years of age, strong, robust young man, was sent to me last winter by Dr. Frank Cary. History of severe cold and sore throat.

Laryngoscope examination showed large abscess of the larynx. After applying cocaine, I evacuated with guarded lancet; considerable choking and coughing. Next day the abscess had refilled. I then introduced a cantery electrode in the place of former puncture and thus formed a round opening with some destruction of tissue, hoping thereby to facilitate drainage. I then washed out thoroughly with peroxide of hydrogen. There was no further refilling and the patient made a rapid recovery.

Case 3.—Mr. W., 50 years of age, small stature, emaciated, consulted me in October, 1890, on account of difficult deglutition. He informed me that he had experienced an increasing difficulty in swallowing, and at that time it required constant effort for over an hour to swallow a cup of coffee, and that no solid food had been taken for several weeks. He said he must get relief very soon or else die of starvation, and his appearance justified the statement.

Inspection of the outside of the throat revealed the fact that in the act of deglutition the larynx did not ascend to the normal extent, and that it seemed bound down and was less freely movable than normal. There was no infiltration of glandular structures in the neighborhood. The patient was free from pain and the family history was good.

On making a laryngoscopic examination, a large lobulated growth of a whitish opalescent appearance was seen apparently springing from the œsophageal opening, and acting as a valve, while one of the larger lobes projected forward, between the arytenoids, and appearing to prevent the epiglottis from closing the larynx completely in deglutition, and seemed to explain why the fluids, as he expresses it, "went the wrong way" and "choked him."

I applied a 10 per cent. solution of cocaine to the entire larynx and, after about six minutes, made a more thorough examination with the probe, and found the growth to spring from the posterior wall of the œsophagus, immediately be-

hind the larynx. Thinking that possibly the growth, by its size and location, mechanically prevented the entrance of food, I determined to remove it. This I had no difficulty in accomplishing, using the galvano-cautery snare, removing it in four pieces, there being neither pain nor hæmorrhage during the operation. There was no reaction of any consequence subsequently. On attempting to pass a bougie into the œsophagus, I found a stricture at the upper part, although deglutition had been somewhat facilitated by the removal of the growth.

Microscopic examination revealed the fact that the growth was a ring-shaped carcinoma. After this time I dilated the stricture about every five days and twice each day I passed the stomach tube, giving the patient each time nearly a quart of milk, together with two eggs. Sometimes peptones were added instead of eggs, and for the last two months an ounce of brandy was given with each feeding, at the patient's request. For a short time the patient gained somewhat in weight, and quite materially in strength, going about the city freely and seemingly happy, and he said free from pain. At home he took some coffee and occasionally a little soup or broth. This treatment was continued for several months, when the patient died.

One interesting and troublesome feature of the case might be mentioned. From first to last it was impossible to introduce the stomach tube without the aid of the laryngoscope, thus necessitating personal care of the patient.

There was no return of the growth in the laryngeal cavity but the extension was downward.

70 State Street.

FRACTURE OF THE THYROID CARTILAGE.

BY GEORGE L. MORGENTHAU, M.D.,
OF CHICAGO.

ASSISTANT AT PROFESSOR SCHNITZLER'S POLICLINIC FOR DISEASES
OF THE THROAT AND CHEST, VIENNA.

Since Arbuthnot Lane¹ (1885) drew the attention of the profession to the frequency of fractures of the hyoid bone and larynx, several cases have been reported which tend to confirm his statement, that these fractures sometimes produce such light symptoms that they can be overlooked. Formerly, the prognosis was considered much graver. Gurlt² had (in 1864) collected 68 cases, of which 47 ended fatally, and only 21 recovered. Even excluding those in which the injury was caused by an attempt on the patient's life, or where some additional accident complicated matters, 21 died, and but 13 recovered. Fischer³ pronounces every

fracture of the larynx serious. Later observers, however, contributed statistics which are more encouraging. The most recent publication, by Sakolowski,⁴ describes a severe case with recovery. In it will be found a summary of the literature on the subject, statistics, etc.* Although the case I had occasion to observe is an uncomplicated one, or rather because it shows how exceedingly light the symptoms resulting from a fracture of the thyroid cartilage can be, I think it worthy of publication.

The patient, a fairly intelligent, robust artisan of about 40, came to Professor Schnitzler's department in the Wiener Allgemeine Poliklinik on account of hoarseness. On being questioned how long this had troubled him, he said that some three months ago, while bending over a balustrade, he was struck on the back of the head by a descending, heavily loaded elevator. His neck was pressed between the lift and the bar. He was immediately attacked by a coughing spell, expectorated a little pure blood, and became aphonic. There was no pain, but the swelling about the neck induced him to go home and make applications. The next day he could go to work again, hoarseness being the only reminder of yesterday's accident. It was the hoarseness on account of which he came to the Polyclinic, not having found it necessary to consult any physician meanwhile.

While inspection revealed nothing abnormal in the anterior part of the neck, upon applying the finger to the angle of the thyroid cartilage, the left ala receded. By rubbing the two fragments together, distinct crepitus could be heard and felt. Further palpation showed that the left wing of the thyroid cartilage was fractured longitudinally, the line being slightly irregular, and about $\frac{1}{8}$ of an inch from the angle of the cartilage. All other parts, especially the hyoid bone and cricoid cartilage, were examined carefully, but appeared unharmed. The condition of the interior of the larynx was as follows: The epiglottis was omega-shaped, slightly overhanging. Both ventricular bands were much swollen, but did not look angry. The vocal cords could not be seen. Even in phonation, only a little portion of the posterior ends could be perceived. During the act of phonation the ventricular bands approximated, apparently producing the hoarse voice. An accurate opinion of the lesions in the larynx cannot be formed. The mucous membrane must have been lacerated, since the accident was immediately followed by hæmoptysis. The rent in the membrane, however, could not have been long or deep, or emphysema would have set in. According to statistics, there is emphysema in most of the cases, sometimes extending to the extremities. Possibly, also, the anterior attachment of the vocal

¹ Arbuthnot Lane, *British Med. Journal*, March, 1885.

³ Fischer, *Deutsche Chirurgie*, Lief. 34.

⁴ Sakolowski, *Berl. Klin. Woch.*, No. 40, 1890.

cords was severed, and they could not be seen because they could not contract, not only because they were hidden by the ventricular bands. Another interesting question (also from a medico-legal point of view in cases of assault), is why, in this case, the line of fracture was vertical, and in or near the centre. Gurlt's experiments demonstrate that vertical fractures are possible when the larynx is compressed antero-posteriorly, as in this case. Possibly, ossification in the cartilaginous tissue had advanced to just the line of fracture. And the absence of the youthful elasticity—due in turn to the deposit of bony matter—is a predisposing moment (Hoffmann⁵). To be sure, the elasticity is not so great as to protect the larynx against every injury by external force. Figures show that youthful individuals are not at all immune against fracture of the larynx, although partial ossification predisposes to injuries. As this patient is over 40 years, ossification has undoubtedly begun. According to Patenko's⁶ observations, the elasticity is not diminished before the thirtieth year, and ossification varies very much, also, in regard to the region where it commences, and to its extension. Another explanation applicable in the present case is offered by Gurlt. When the line of fracture is to one side, this might be due to the suture which is formed by the ala of the thyroid and a narrow, thin cartilage sometimes found between the two wings.

The only indication in this case, at the time the patient came to the Policlinic, might have been the alleviation of the hoarseness. The fracture caused him no inconvenience excepting the hoarseness, which did not hinder him in his work. We could not, therefore, in conscience advise him to undergo an operation, although the case might be considered well adapted for sutures. There was no vestige, here, of the formation of a bony callus after three months, though Lane demonstrated a specimen in which bony union had taken place. Perhaps the increased irritation by the wire sutures might have proved a favorable factor in bringing about such a result. Even fibrous union would justify an operation in some cases. As to the advisability of using sutures, the opinions of surgeons are divided. Fischer reports that all kinds of wounds and injuries in the upper air passages have healed as well without sutures as with them.

Generally, tracheotomy has been performed when the surgeon was called in shortly after the accident. Threatening dyspnoea will make this operation necessary in the majority of cases. Besides, in fracture of the cricoid cartilage, the canula tends to immobilize the fragments (Clarac⁷). Both indications might be met, in fracture

of the thyroid cartilage, by O'Dwyer's permanent tubes. Intubation ought certainly to be tried in appropriate instances. Adaptation of the fragments will often present great difficulties, either when done from without through the tracheotomy wound or an incision, or possibly from above by aid of forceps. Complete rest, ice-bags on the wound, and vapors, are certainly of great benefit. The case described proves that tracheotomy is not always necessary. After only a day's rest the patient returned to work, without ever experiencing pain, or any inconvenience excepting hoarseness.

Vienna, July 1, 1891.

A BRIEF COMMUNICATION ON NASAL VIBRATION (MASSAGE) WITH REPORT OF CASES.

BY NORVAL H. PIERCE, M.D.,

OF LONDON, ENG.

At the Tenth International Medical Congress a paper was read before the Laryngological Section, which at once attracted attention, first, because it sought to introduce a novelty into our therapeutics; secondly, because it had for its scope and promise the cure of a class of diseases which have been regarded as nearly or altogether incurable. I refer to Dr. Brown's paper on Vibratory Massage of the Nose,¹ etc.

In order to refresh the memory of the reader I will take the liberty of presenting an extract translation of the above mentioned contribution.

The two massage movements employed are known according to Dr. Kellgrew (London) as *effleurage* and vibration.

By *effleurage* is meant a *stroking* movement superficial or deep, the force of which varies from a scarcely perceptible touch to distinct pressure.

By *vibration* is meant a light, rapid trembling movement, having its origin in the elbow joint and which is transmitted by the palmer ends of the fingers to the point of operation. The motions occurring in the relaxed wrist joint are abduction and adduction, while the hand itself remains in uninterrupted contact with the surface operated upon. The whole procedure is characterized by a lightness, rapidity, and elasticity of touch. The number of vibratory movements varies from 200 to 300 per minute.

In order to apply this treatment to the nasal cavities, a copper sound is necessary. The one recommended measures twenty cm. in length, and has a diameter at the larger end of two mm. The end which is introduced into the nose is finished with a ribbed head to which cotton may be attached. This cotton may be immersed in

⁵ Hoffmann, Wiener Med. Woch., Nos. 44 and 45, 1886.

⁶ Patenko, Vierteljahrschr. f. gerichtl. Med. von Eulenber, Bd. xli.

⁷ Clarac, Gaz. des Hôp., September, 1890. (Int. Centralbl. f. Laryngologie, etc.)

¹ Massage, beziehungsweise, Vibrationen, der Schleimhaut der Nase, der Nasenrachenraums und des Rachens. Dr. Michael Braun, Triest, Oestreich.

various medicinal solutions hereafter to be specified. The sound is held in the hand like a pen—i. e., between the thumb and first and second fingers—and the vibrations carried on as above described.

First, the floor of the nose is vibrated, then the inferior meatus and turbinated body, then the middle and superior, along their entire length, after which comes the septum. The Eustachian prominence may also be treated in the same manner, as well as the orifice of the Eustachian tube itself.

The number of fresh sounds used in a single case varies. In a late letter which I received from the author he says that he uses as many as twenty in one séance.

Strict cleanliness must be observed; all encrustations and discharge must be carefully removed and the vibrations carried to every part of the nose that is reachable. The vibrations last from one-half to sixty seconds, according to the patient's power of resistance.

Various solutions are recommended to be used in connection with the treatment. If there is hypersensitiveness the nasal mucous membrane is first painted over with a 20 per cent. cocaine solution. Subsequently the following medicaments may be used: 10 per cent. menthol vasaline ointment, 10 per cent. iodo-glycerine (iodine 1.00, kalium iodid. 1.00, glycerine 10). Sublimate (1 pro mil), lanolin, vasaline, balsam of Peru.

Dr. Brown has treated 1,000 patients by this method of treatment, and the most various nasal pharyngeal and laryngeal diseases have been comprised within this number. Perhaps the most striking results were obtained, it is said, in foetid atrophic rhinitis. The disease very soon loses its foetor, and the mucous membrane is restored to its normal condition, while the *atrophic turbinated bodies return to their normal proportions*.

In order to test the efficacy of this therapeutic mode, six cases of foetid atrophic rhinitis were selected from Dr. Ottocar Chiari's ambulatorium at the K. K. Algancinca Krankenhans in Vienna, and placed under my care. These cases were carefully and conscientiously treated every day, with the exception of Sundays and holidays, for two months. At the end of that time I was called away by other duties, but the treatment was carried on for two more months. The directions given by Dr. Brown were carefully observed. Before the vibrations were commenced each patient received a thorough nasal douche or bath of one-half per cent. carbolic acid sol. and the nose was carefully inspected to see if any secretion or crusts remained. If so they were removed by the dry pledgit. The cotton with which each vibration was carried on was first

immersed in iodo-glycerine sol.; each séance lasted from twenty to sixty seconds.

Following is a brief summary of the cases with the results obtained:

March 2, 1891.—C. S. aged 29. The patient came to the ambulatorium in the middle of September, 1891. She was then suffering from advanced atrophy of both inferior turbinated bodies, accompanied by profuse secretion and formation of foetid crusts. For two months from entrance the patient received a daily douche of one-half per cent. salt solution, and the nasal mucous membrane was painted with iodo-glycerine, which treatment was followed by a decrease in the amount of secretion. The vibrations have been carried forward since the middle of October. The patient says the discharge from the nose is much improved, but we can see no change in the atrophic condition.

M. P. aged 26. Patient complains that for three years a disagreeable odor has tainted her breath, and that she has had a profuse nasal discharge. Inspection disclosed marked atrophy of the lower turbinated body of the left side, and formation of crusts. Since the middle of November the patient has had nasal douche three times daily, and once a day penciling with iodo-glycerine. Under this treatment the foetor diminished, together with the crusts, but the secretion was never altogether absent. Since November the vibrations have been employed. At this time the secretion is very slight in quantity, but there is no appreciable improvement in the atrophy.

S. A. aged 23 years. Patient has been treated since September with nasal douche and iodo-glycerine. She suffers from advanced atrophy of both inferior turbinated bodies; the right is the more advanced. Foul smelling crusts are also present. Vibrations since November. The secretion is improved more under this treatment than under previous method. Atrophy unchanged.

C. P. æt. 15. Patient has been a year at the clinic suffering from rhinitis atrophica. The inferior turbinated bodies entirely disappeared, and only a small portion of the middle ones remain. There is foetor, profuse secretion and formation of crusts. The treatment has been nasal douches and penciling with iodo-glycerine until November, 1890, when vibrations were commenced. The odor and crusts formation have disappeared. The atrophy, however, is unchanged.

M. L. æt. 14. Patient has been coming to the ambulatorium for a year. There is atrophy of left lower and middle turbinated bodies, much secretion, crusts and odor. Before commencing the vibrations the treatment was much the same as that employed in the other cases, but the former has not proved superior to the latter. The atrophy is unimproved.

N. A. æt. 20. Patient complains of having

had a disagreeable odor from the nose for a long time. Inspection shows atrophic rhinitis. Patient has taken nasal baths at home for some time. Came to clinic in January, 1891. The vibrations in this case were followed by entire disappearance of the fœtor and diminution of secretion, but the atrophy remains unchanged.

From these cases and results we may draw the following conclusions:

First—To the cleanliness which is made so essential in this mode of treatment, are due most of the speedy cures or reliefs of disagreeable symptoms, i. e., fœtor, secretion, etc.

Second.—The vibratory movements themselves may be indeed of some benefit, inasmuch as they are stimulating to the lymphatic and vascular system, but

Thirdly we must believe from the above results that the vibrations have little or no action in regenerating atrophic tissue.

In conclusion I have to express my sincere gratitude to that eminent teacher, Dr. Ottocan Chiari, for his permission to publish these results as well as for many other kindnesses.

London, April 22d. 1891.

A NEW UNIVERSAL DOUBLE-ACTING SNARE.

BY CHARLES A. BUCKLIN, A.M., M.D.,
OF NEW YORK.

The good principles of all similar instruments have been combined in this snare, and their inherent defects have been obviated.

The wire is attached to a solid stylet, the objections to which are overcome by the powerful ratchet motion which draws it. A screw motion is also attached to the same stylet, thus enabling the operator to use a very slow-cutting snare, where hæmorrhage is feared, while the ratchet

motion provides a rapid-cutting one where there is no reason to expect hæmorrhage.

The handle and ratchet motion may be detached at pleasure, leaving an instrument suitable for the slow strangulation of a very vascular growth.

The instrument has a straight tip for the nose and curved tips for reaching the larynx and naso-pharynx through the pharynx.

In curved canulas all attempts to use flexible stylets under severe traction are dangerous, as they must break sooner or later in making the transit of the curve.

With this wire *écraseur* every benign neoplasm or hypertrophy found in the nose, naso-pharynx or pharynx can be removed at a single sitting in a manner which commands the approval of the most conservative operator.

This instrument also fully meets all the requirements met by Stoerks' laryngeal guillotine or wire *écraseur*, and furnishes one not provided with laryngeal forceps with a simple and effective means of extracting many foreign bodies which lodge in and about the larynx.

If the instrument is firmly secured at the detaching joint, the wire properly fastened, and the clearances of the ratchet under-strain are $\frac{3}{4}$ of an inch, it will never fail to cut any growth the loop embraces.

The straight canula is armed with wire by passing it through the eyes of the slightly projecting stylet from opposite sides. The required loop having been formed, the stylet is drawn by the ratchet motion, and the projecting ends of the wire are cut.

The curved tips are armed with wire by bending one-sixteenth of an inch of the end at an angle of forty-five degrees. It is then passed through the first eye of the stylet into the opening at the curve of the canula, with the convexity of the wire impinging on the concavity of the canula. Emerging sufficiently to form a loop, it is returned through the curved canula, with its convexity impinging on the concave surface of the canula. When the wire appears at the opening, it is twisted until the bent point is opposite the second eye in the stylet, which it will enter easily, and the loop is complete.

By the pressure of the thumb on the tip of the instrument, the wire loop, after having been drawn, can be returned instantly to position for further operation through any of the tips.

For further particulars and history of steel wire snares, see *New York Medical Record*, July 4, 1891.

THE STERILIZATION OF MILK AND THE STATUS OF OUR KNOWLEDGE UPON THIS SUBJECT.

Read in the Section of Diseases of Children at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1897.

BY HENRY KOPLIK, M.D.,
OF NEW YORK.

In presenting this subject, I feel that I am going over ground well elaborated before me, yet even in the face of this, it is somewhat surprising to find the lack of systematic idea entertained by physicians upon the subject of milk or its sterilization. This most important innovation upon infant feeding has, even in our journals, been granted faint praise in occasional paragraphs.

Though the work done thus far in this field has been most painstaking and scientific, it has not fully reached those for whose benefit these investigations are mostly undertaken,—the medical public. There are scattered through the French and German literature some very classical articles upon this subject, but no English writer has of late attempted to systematize and classify the ideas presented. If this article will deal with some scientific and abstruse data, it will endeavor to bring these in direct relation with our daily practice and therapy. For a long period past, the author has been going over old and recent ground, and this paper will endeavor to formulate the landmarks of our knowledge in this field.

Milk as it exists in the udder of a healthy cow is devoid of bacteria, as is also that of the human subject; germs of an offending nature reach the milk after it has left the animal. Speaking only of healthy animals and their milk, it is a matter of daily observation that various samples of milk will contain varying quantities of foreign matter, due, no doubt, to varying conditions of cleanliness at the first dairies. Soxhlet and Renk called attention first to the palpable detritus to be found in milk, and this has been often confirmed by my own observations. Aside from straw or dirt from the hands, if milk is allowed to stand in large quantities, small black specks may be seen at the bottom of the containing vessel, if this be glass. These small specks are mature from the udder or teats of the animal; thus it is easy to see how even healthy milk may contain very obnoxious elements. Renk found that different dairies varied in this respect as to the quantity of sediment. Here, in New York, I am happy to say that with care, we can obtain a milk moderately free, though not entirely so, from these elements; but in large quantities (a year ago) I have during the summer season seen these black specks in milk. Thus the bacteriology of milk must vary vastly with the varying amount of care or cleanliness with which the milk is col-

lected,—and results of different authors will also vary, according to the source from which the milk is obtained. But the main principles are fixed, and can guide us in our practice.

If milk be allowed to stand at the ordinary temperature of the room either in summer or winter, it becomes "sour"—acid in reaction; there is a disturbance noticed in the consistency and appearance due to a precipitation or coagulation of the caseine elements of the milk and their separation from the fluid portion of the liquid. This is the acid fermentation of milk found under the normal conditions, and in ordinary milk, and was systematically studied by Pasteur, who described the "ferment lactique" or lactic acid bacillus as the cause and prime factor in this change. The rapidity of fermentation must vary with the temperature and varying conditions of bacteric invasion of the fluid. During the heated term, these conditions are presented at their best, and it is then that the above changes set in most rapidly.

In order to understand the true value of our present methods in dealing with artificially fed children, it is necessary to go over some historical ground, and I promise only to take you where my own studies and observations have led me.

The most admirable work of Hueppe upon milk, its decomposition by microorganisms, is known to you all. I will collect some data from this article first in my resumé.

As an example of the older doctrines upon the decomposition of milk, we may mention the views of Stahl, who writing in 1697, considered fermentation and putrid decomposition as analogous processes, fermentation being only a variety of decomposition. He assumed that in fermentation there was the formation of new combinations and the cause of the decomposition resulted from the transmission of molecular movement to easily decomposable combinations. The great advance in our knowledge of lactic acid fermentation, presupposes that once for all, lactic acid is a very characteristic combination, and on this ground, its separation from other decompositions. Scheele, in 1780, first discovered lactic acid in milk with its great resemblance to acetic acid. It will not aid us to go into a long resumé, so that our purpose will be subserved, if we next look at the work of Pasteur, who, in 1857, described a ferment which was always present when lactic acid resulted from sugar in organic fluids. He described this ferment minutely as small spheroidal bodies forming short links. With this theory of Pasteur, the lance was again taken up for the bacteric as against the chemical theory of fermentation. Later, 1858, Pasteur proved that in various fermentations if lactic acid be present and formed the lactic acid ferment was always present, although there were

numerous other and with difficulty isolated ferments. By excluding the air, his fluids remained unchanged, so that he concluded that the organisms were derived from the atmosphere and did not result from spontaneous generation. He found, what is important in relation to sterilized milk, that in spite of subjecting milk to a temperature of 100° , coagulation resulted, not with acid but alkaline reaction. There was no lactic acid ferment but "infusoria" (potato or butyric acid bacilli). At a temperature of 110 to 112° and $1\frac{1}{2}$ atmospheres, there was a destruction of all life, no infusoria found, and no fermentation resulted. Failure to sterilize the milk was due not to spontaneous generation, but to the presence of a very resistant organism.

Schroeder and Pasteur came simultaneously to the conclusion that milk is difficult to sterilize, because it contains organisms which are very tenacious of life. But while Schroeder assumed that these organisms were present in the milk itself, Pasteur thought they were derived from the surrounding atmosphere. Pasteur first (1861) divided the butyric acid ferment from that of lactic acid, and minutely described the butyric ferment, which he called "Vibrio," and classified it among the infusoria (bacilli). The lactic acid ferment was also minutely described. Lister in 1878, established that the particular organism which he named *bacterium lactis* caused the acid fermentation of milk, and he by a method of dilution by which each drop of his fluid held a ferment germ, caused sterilized milk to undergo lactic fermentation with acid reaction; he described this organism also very minutely. He proved that other fluids, as water added to sterilized milk, caused other fermentations as butyric, but not lactic acid fermentation. Up to this time, the doctrine promulgated by Schroeder, Schmidt, Hoppe-Seyler, that though an organized ferment may cause lactic fermentation, yet under all circumstances, this was not necessarily the case, but that there were lactic fermentations dependent upon a chemical ferment preëxisting in the milk and derived from the mammary gland.

W. Roberts, in 1874, succeeding in retaining milk drawn from the breast into glasses free from fermentation, and Lister and Cheyne had similar results. Meissner first established in a scientific way, that milk as other fluids, could under certain precautions be drawn from the animal and retained free from decomposition, that is, that decomposition was due to organisms which reached the fluid from surroundings and air. Therefore, the milk in the presence of antiseptic means and high temperature acts not like an enzymatic solution, but as a medium which contains organisms capable of certain resistant powers. Therefore, the cause of lactic acid fermentation is an external one always, and the germs gain access in the stalls and storage

places of the milk. These are only avoided with such caution as to give rise to the idea, as formerly in vogue, the milk itself contained the primary cause of fermentation in the form of a chemical substance.

I have in the above given a short resumé of the principal steps which led to the closer bacteriological study of milk; yet it is surprising that though Pasteur so long ago established the fact that the acid fermentation of milk could be avoided and gave data, no systematic attempt at milk sterilization was thought of in connection with infant therapy, until the work of Soxhlet, preceded by that of Hueppe, appeared, and this is explained by the enormous impetus given to modern bacteriological researches by the doctrines and methods of Robert Koch, which has permeated every branch of our professional work.

When we subject milk to heat, we have to meet the insurmountable obstacle of an organic fluid which not only may contain bacteria which are resistant to a considerably higher temperature than that of ordinary steam, but by the nature of its composition, milk is apt to protect to a very effective degree contained bacteria from the action of the externally acting heat. Again, milk, if heated to too high a temperature, changes in color, and there is a separation of certain elements (butter), and a change in others (caseine and sugar elements). From the temperature of 75° Celsius, there is separation of the serum albumen of the milk. The caseine loses its coagulability to rennet, and at 85° , amounts which for the raw condition are found sufficient to act, cease to be of any effect. J. Munk found that in milk sterilized under three atmospheres, four times the ordinary quantity of rennet was necessary in order to act satisfactorily. Hueppe has confirmed this, as also, in another manner Dr. Chapin, who has, it seems, come to the independent conclusion that the caseine of the milk suffers a change in sterilization (*Med. Record*, 1890).

Hoppe found that milk sugar at 80° to 90° suffers a change, which increases at 100° to such an extent that, after two hours' exposure to this temperature, milk and milk sugar solutions become of a brownish tint. At a temperature of 110° this is more marked. Pasteur found that at a temperature of 110° to 112° , and $1\frac{1}{2}$ atmospheres, there is a slight oxidation of the fats in the milk, which gives it a tallowy odor.

Hueppe concludes that between 75° and 100° , the milk is gradually changed in its chemical composition, but these changes are of such a nature that the digestibility of the milk is scarcely diminished, and its taste and odor but little changed. A temperature of 140° may coagulate the caseine (Hoppe), and at 120° coagulation begins to set in, if this temperature is kept up for any length of time.

I have here tubes in which the milk has been subjected to only the Pasteur temperature, $1\frac{1}{2}$ atmospheres and 112° , with only the brown discoloration to be noticed, from inspection.

The above facts are and will be useful in guiding future work upon this subject, and the law laid down by Hueppe still remains true, that from a physiological standpoint, milk is best sterilized (if possible) under a temperature of 75° C., but it may be admissible as far as 100° C.

We have of late years been recipients of many suggestions as to sterilization, but if we look at the mass of matter and suggestions, we will find that though the above principles still hold good, and have been established for decades, the only direction toward which the ingenuity of physiologists and clinicians has exerted itself, has been mostly in the empirical direction of some form of "apparatus." Thus, in the great struggle to invent some unique form of cooking utensil, some great truths have been lost sight of and buried in the débris of apparatus. The sterilization of milk may be performed, according to Pasteur, absolutely, at a temperature of 110° to 112° and an increase of $\frac{1}{2}$ an atmosphere. This has its objections, and these are, as it seems, very formidable, not only from an æsthetic standpoint, but the physiological also. The caseine, which even at 75° begins to change, certainly approaches the coagulation point (from heat alone) at the Pasteur temperature. Not only this, but there is reason to believe that such caseine is even less acted upon by the weak stomach juices of the infant, than we at present are led to believe from physiological experiment. Another method of sterilizing the milk is also a gift of the genius of Pasteur, and that is the so-called "Pasteurization" of milk. In the *Zeitsch. f. Hygiene*, Vol. viii, Heft. 2, Bitter has attempted this method. Milk is heated in large masses up to 70° to 75° , and maintained at this temperature for half an hour, then rapidly cooled; this is done by passing the milk over coolers until the temperature of 18° to 19° is attained. The milk will keep quite well for some time—twenty-four to forty-eight hours; but this scheme is scarcely practicable. What I mean by this is, that no means are as yet at our disposal to place this in every household. Strub (*Bact. Centralbl.*, 1890) gives details of a method by which milk heated to 70° , and very rapidly cooled to 40° or even 20° Celsius for about five successive times, has given satisfactory results in mercantile departments of milk industry; but the apparatus necessary for this, it is needless to say, must be very elaborate.

We next take up the sterilization of milk at the heat of boiling water, in a water bath, that of Soxhlet, of Munich. To this man will always remain the great merit, not of having done anything new, but of practically placing milk preservation within the reach of every housewife,

and of putting into practice certain principles for whose reception the therapeutic world was not hitherto prepared, though these principles were well-known. Soxhlet (*Munich Med. Wochen.*, 1886, p. 253), brought forward in a striking way the advantages of protecting the infant from the acid fermentation of milk, and he eliminated it very easily by, as you all know, placing the nursing-bottles in boiling water and leaving them thus for forty minutes. He also called attention to external sources of uncleanness at dairies, such as pots, hands, and the state of the udder of the animals. Soxhlet, at that time, said that milk thus treated could be kept at the room temperature three or four weeks without spoiling or becoming acid. This I will show is true to a certain extent. It is a misleading statement. He gives some interesting data as to the time and temperatures at which ordinary acid coagulation of milk takes place. Thus: at 35° C. in 19 hours; 25° C., 29 hours; 10° C., 208 hours; 0° , 3 weeks. In any acid milk, fermentation at 35° C. results in the production of 3 per cent. of alcohol, almost as much as that contained in beer. Soxhlet placed great stress upon his peculiar stopper, which I will take up later. It remains that the Soxhlet plan is that of the boiling water bath, and it has its drawback in a certain amount of irregularity of heat conductively, by which the methods and results are less uniform than that of the next method, which I think is the most satisfactory, and that is the sterilization of milk by the plan first advocated by Hueppe in 1884 (*Mittheilungen aus der Kaiserlich gesundheits amt*). By this method, the milk is sterilized in small quantities, but the water does not reach the containing flasks, and steam alone is the means of sterilization. The results are certainly more uniform by the sterilization in steam. By this uniformity, I simply desire to mean that we are first certain that every flask, being surrounded by steam, receives the benefit of the same quantum of heat, 212° , and the latent heat of steam. The conclusions of Hueppe were that steam is most satisfactorily and rapidly generated in the ordinary protected tin pot of Koch, and milk which in reagent glasses had to be subjected to the boiling bath for one hour, was easily protected and sterilized from acid fermentation in twenty minutes in the live steam. This is of great economic, as well as of scientific importance, and is another guiding-post for future work. Occasionally, in this short space of time, the milk sterilized in reagent glasses would subsequently coagulate, but in forty-five minutes the sure sterilization resulted. Hueppe noticed that in milk which was certainly sterilized at 100° , there appeared gradually a sediment, which he thinks contained the separated albumen and coagulated caseine, and the milk above this sediment was more watery than the milk sterilized below 75° .

Thus the milk sterilized under 75° differs from that sterilized at 100° in the more marked appearance of sediment, and its insolubility. Nægeli noticed changes even in milk heated to 110° to 120° after four to six months, both in appearance and taste. Meisl (Hueppe) records appearance of pepton, tyrosin and leucin, and ammonia, in milk apparently sterilized. As far as our knowledge goes, milk may be absolutely protected from future *acid fermentation* by subjecting it to a temperature of 100° in live steam.

I will ask you to notice that there is another fermentation of milk, the alkaline concerning which a great deal of misunderstanding exists, but about which there are certain well known facts to which I beg your present attention.

The acid fermentation of milk is brought about chiefly by a species of microorganisms called by the author, Hueppe, who very closely studied its growth and behavior, the bacillus of lactic acid fermentation of milk. The milk as it reaches the purchaser is very rich in microorganisms, but this one alone is chiefly responsible for the sour reaction of spoiled milk. I show you a culture of this in various media and fluids, and you will see it was well described by Hueppe.

I do not think this is the place for close bacterial descriptions, but let me call your attention to some very interesting data. This microorganism is of small oval form occurring single and in pairs. It does not fluidify gelatin and grows upon all media, when it is inoculated into absolutely sterile milk (milk subjected to temperature of 112° and $1\frac{1}{2}$ atmospheres); there is in a short space of time a coagulation of the casein elements, but what is most interesting, is the accumulation of bubbles of CO_2 gas at the top of the milk and near the top. I show you a potato culture of the bacillus of lactic acid and you can see the bubbles of CO_2 in this culture also. The coagulum of the milk is peculiar, in that it is traversed by fine spaces and cracks, in which are entrapped bubbles of CO_2 . The spaces become larger and wider; the coagulum contracts after a few days. In these spaces there is a serous fluid. The microorganism measures $1-1.7 \mu$ long and $.3 \mu$ to $.4 \mu$ thick: the bacteria may reach 2μ in length. Hueppe thinks they contain spores, especially in sugar solutions; he also found these spores in sour milk. (But this is difficult to reconcile with some statements of Loeffler, which will be referred to below.) This organism grows from 10° C. up and has its maximum growth between 35° and 42° ; it also stops growing and the acidity no longer forms at 45.3 to 45.5° .

It is not necessary to go into further details, but we must remember that the heat of steam, while it may in twenty minutes destroy the lactic acid bacillus, does not entirely destroy the spores, so that a prolonged steaming is necessary to ab-

solutely render these spores innocuous (forty-five minutes). Thus, as mentioned, Hueppe found that test tubes of milk sterilized for twenty minutes in steam, did not always remain free from acid fermentation, the spores subsequently growing and causing acid fermentation, and I myself have seen tubes heated with steam for twenty minutes undergo subsequent acid fermentation in the thermostat, turning the litmus, which was mingled in some of the tubes, red, and finally decolorizing it. The lactic acid bacillus of milk is able for a time to resist the temperature of steam.

It has been noticed (Pasteur, Nægeli, Hueppe, Meyer, Loeffler) that milk which has apparently been thoroughly sterilized, will after a space of time, varying in each case with circumstances of temperature and previous state of the milk, undergo changes and a distinct precipitation, or rather coagulation, sometimes with the formation of peptone, leucin and tyrosin. Pasteur, as above mentioned, established that these changes always occurred in the presence of an alkaline reaction; when milk was sterilized at 100° C. acid reaction was never present. He named the bacteria thus found in the milk so decomposed, infusoria; we know now that they are always rod-shaped or bacilli. Acid reaction is never present except to a slight degree at first with the butyric acid bacillus (Hueppe), but alkaline reaction soon results even here. Hueppe first described a butyric acid bacillus (aerobic) which he found in milk which had been subjected to three atmospheres of pressure with corresponding high temperature. This milk was decomposed and contained a bacillus which was very resistant and could withstand very high temperatures; even much higher, as you see, than the $1\frac{1}{2}$ atmospheres of Pasteur. This bacillus or microbe contains spores and it is in this the resistance to temperature exists. Hueppe described this bacillus minutely, and we are able to find it to-day in milk (Loeffler). I have been able to isolate a bacillus very much resembling it with others from milk sterilized by various apparatus and have found it in a sample of milk which had been sterilized by the Escherich new large sterilizer, in which the milk is sterilized in quantities of about a quart. The milk was taken from the sterilizer on the second day after sterilization. The milk was slightly alkaline and subsequently became very alkaline in reaction with small and large soft clots of a peculiar odor. This is nothing new, but it will explain other facts hereafter to be stated. The ordinary potato bacillus (bacillus mesentericus vulgatus of Flügge) was also present at the same time. Loeffler (*Berlin. Klin. Wochen.*, 1887) not only confirmed Hueppe's investigations, but found other bacteria, all varieties of the ordinary potato bacillus, in milk which had been subjected to the temperature of steam for ten min-

utes. This temperature destroys the bacilli and other bacteria, but not the spores, except those, this not always as Hueppe found, of lactic acid fermentation. These spores subsequently decompose the milk through their proliferation, but always with alkaline reaction. The coagulation of the caseine is also of a more flocculent character. There are first the ordinary potato bacillus, the bacillus *mensentericus vulgatus* of Flügge, then the white bacillus, a subvariety, as also the gummy (bacillus *liodermos* of Flügge), and a third variety of the same organism which Loeffler calls the white bacillus. It would be sufficient to mention these here and to show how they grow only in sterilized milk. In sterilized milk, the potato bacillus (first described by Hueppe) after a few days in the thermostat causes the appearance of a clear zone underneath the cream zone at the top of the milk. This zone varies from a clear to a cloudy one, according to the varieties of potatoe bacillus which is inoculated or growing in the milk. Crystals of leucin and tyrosin appear at the bottom, in case of the white bacillus. The reaction of the milk is distinctly alkaline. The most important lesson to be learned from the above is that milk well sterilized by steam with any apparatus (Koch, Soxhlet, Escherich, Arnold steam cooker) will after a time decompose with an alkaline and no acid reaction. The time at which macroscopic changes appear has been regarded by some authors as the surest sign of decomposition, but they have mostly, even in late times talked of the milk becoming sour, as you see it does not undergo acid fermentation but alkaline fermentation.

Strub (*Centralbl. f. Bact.* 1890) has experimented with almost every known apparatus and was able to establish even immediately after sterilization the potato bacillus in the samples of milk which she used. She also established that repeated fractional sterilization in a Koch apparatus was not sufficient, even after many repeated steamings, to entirely destroy this bacillus (its spores).

Especial interest is the behavior of bacteria when inoculated into milk (sterilized) to which litmus (1-10) according to Liber and Marpmann, has been added. There is a gradual decolorization of the litmus in some, showing that there is something formed aside from pure alkalinity or acidity, which has oxydation action upon the litmus.

I show also that the lactic acid bacillus turns the milk with litmus red and finally decolorizes it. The streptococcus pyogenes turns the milk acid, litmus red and finally decolorizes it. The typhus bacillus (Loeffler) turns litmus (sterilized) milk slightly red. Tubercle diphtheria and cholera microbes grow very well in milk without causing any marked change in the same. The substance which with the lactic acid bacte-

ria and potato bacillus causes decolorization, is not as yet established.

The object of this paper being a review of our knowledge of sterilized milk and its value, as also the writer's observations in this line, it is foreign to consider here the decompositions or contaminations of milk as we find it in the stores. The heat of steaming is a protection against those microorganisms which cannot withstand this high temperature and maintain life (tuberculosis, diphtheria), as also against the occasional animal diseases. The blue milk and stringy slimy milk (Hueppe) as also even tuberculous milk, form such a distinct field of work, that a separate paper could be written upon them alone. What practical deductions can be drawn from what has been stated above concerning ordinarily good milk and its sterilization, seems very evident. The first is that milk can be thoroughly protected from subsequent rapid acid decomposition by exposure for a certain time to the temperature of steam, and to accomplish this, the several apparatuses in the market are entirely efficient. It matters very little how many or what variety of microorganisms exist prior to steam, after this only those microorganisms remain capable of proliferation whose spores have a resistance against continued application of 100° C. These in normal milk have been shown to be the butyric acid bacillus and the various varieties of the ordinary potato bacilli. If milk be sterilized and it is found to contain these microorganisms after steaming, their number and capability of doing injury to the milk will vary very much with the conditions under which the milk has been collected. If these microorganisms preexisted in enormous quantities, the alkaline fermentation will under a favorable temperature, set in sooner. If in small quantities, the macroscopic changes of the milk will be scarcely perceptible for some time. If milk could be carefully collected and sterilized at the dairies it might be kept indefinitely after sterilization. Thus, it is seen that even directly after steaming the microorganisms and their spores exist in sterilized milk if they cause the subsequent decomposition. Strub (*Centralbl. f. Bact.* 1890) found that the variety of cork or method of closure of the bottles in childrens' apparatus had very little to do with this subsequent decomposition. Bacteria were present in the sterilized milk, no matter what kind of closure (Soxhlet, cotton, ordinary rubber) was used. But the most important point here to remember and what is known to those who have given thought to this subject, is that the bacteria of the alkaline milk fermentation are very slow to proliferate in sterilized milk; at room temperature the changes in the milk are at best delayed for a few days, even a week, and when the changes are not so marked as to be detected by the eye; such milk has been sold in

the stores and given by others to infants without *seeming* deleterious results, at least not such as are immediately apparent after administration of sour milk. Therefore the influence of bacteria which remain in normal cows' milk after sterilization is of little practical bearing for infants, inasmuch as most families prepare milk daily, and I have never nor can I find data where any one else has found the alkaline fermentation in milk so marked, after, say, forty-eight hours, as to cause macroscopic marked changes. I refer only to the infant apparatus and summer temperatures, and not to those experiments in the laboratory where sterilized milk is inoculated with masses of active potato bacilli spores and bacilli themselves, and specimens of which I show you here. I would not approve, therefore, of the use of any milk in the city which, however well sterilized, was kept for days, and though its color was good, as also its appearance, and it tasted well, is the seat of advanced changes. We find such milk sold in stores where the bottles have been kept even two weeks after sterilization. True, the alkaline fermentation has not been investigated to such an extent that we can with certainty pass upon the deleterious or non-deleterious effect upon infants of the products of this decomposition. It is enough that they take place, and certain alkaloid elements are surely produced, but very slowly, and if the milk is steamed as in the household daily, may be disregarded; but the storage of sterilized milk and its subsequent use after prolonged periods, is to be strongly discountenanced. Therefore in the future, we will know how to interpret those authors who condemn sterilized milk with faint praise by stating the number of bacteria (?) they have found in sterilized milk without stating the whole case. I have had this "clear statement of the case" in view when I undertook the above work, and I hope I have, in a degree, succeeded.

To state that bacteria exist means very little, we must know what variety and their behavior. There is an important practical point which to the writer seems pertinent here: Many physicians have often told me, and no doubt you also, that they find the boiling of the milk sufficient sterilization, or that they cannot see why it is not fully as good as continued steaming. Never was a greater fallacy born of empiricism. Hneppe has shown that milk in small test tubes (10 ccm.) exposed for twenty minutes to the action of live steam at 100° C., are not surely protected from subsequent acid fermentation, and that some of his tubes thus treated turned sour after a time. Here is a tube of milk stained with litmus originally and exposed for twenty minutes to the action of steam in the Koch pot. After placing it in the thermostat at a temperature 35½°-36° C. it turned red in twenty-four hours; this became more marked until full coagulation of caseine re-

sulted, and with decolorization of the litmus. Thus, simple, single boiling of the milk, as it is performed in the kitchen ordinarily, is insufficient to protect milk, aside from facts of exposure of milk to atmosphere and handling subsequently, which enhances chances for decomposition.

Physiological.—There have lately been some experiments, and notably by E. M. Hiesland and H. D. Chapin, upon the digestibility of sterilized milk and the chemical changes in milk brought about by steaming. Their conclusions are so much in accord with those of Hueppe and Munk, their quotation here would only repeat what has been recorded above. Dr. Hirst (*Med. Rec.*, 1891, February), has gone so far as to suggest the addition of milk or some pancreatin powder, before sterilization, in order to digest and help the digestion of the caseine made difficult of digestive solution during steaming. Whether this will prove a valuable suggestion remains to be seen. For myself, I must say I still hesitate to put any digestive powder in the milk of the healthy infant, but in a stomach which proves rebellious, I have been in the habit, like many others, of adding powders to sterilized milk, but have hitherto done this after sterilization and just before giving the milk to the infant. The physiological data of our knowledge in this department of infant dieting are still very meagre, nor has the stomach washing of infants before and after ingestion of foods thus far aided us materially in coming to definite conclusions. Interest has lately been aroused in the discussion of the amounts of milk to be administered to the infant at each feeding. On the one hand, we have Dr. Escherich, who is still guided mostly by the age of the infant, and on the other in our own country, Seibert has advocated the weight as the only criterion for infant feeding; Seibert would reject all past methods and ask his adherents to give certain amounts to certain weights of children. Seibert gives us a table. But these agitations have had their uses, and now attention is being directed more fully to this subject than hitherto.

I have always been guided as follows: I weigh my children always at the beginning of treatment; if their weight comes up to the standard or nearly so, they are given the amount of food which long series of experiments by physiologists and clinicians have proved to us to be adequate for normal children at certain ages. (Vide Fleischman *Pædiatrische studien*, Vienna, 1875). If the infant is markedly atrophic, and as I have seen at three months only weighing less or much less than an average infant at birth, a proportionate amount of food is given. The weight of the child divided by the weight that would be normal, multiplied by the amount of food (grams) necessary to an infant of normal weight and development, at each feeding.

X—weight of infant; Y—weight of normal infant of same age; Z—amount of food at each feeding which is normal to an infant at that age (as far as our knowledge goes).

$\frac{X}{Y} \times Z$ = amount of food to be given at each feeding.

The above digression is warranted by the close connection it bears to any theme of infant feeding, and especially in sterilization, where the size of the individual bottles are a matter of care to the mother.

I cannot close this paper without some practical suggestions, and if they appear trite, they have at least the value of being based upon a large experience. As intimated it would be ideal to sterilize milk in small or large quantities at the dairies, but this has never yet been attempted in this city.

The writer uses as a sterilizer the ordinary wire basket with eight bottles, sold everywhere with the ordinary rubber cork. If the patient can afford it and wishes a rapid steam generator, the patent cookers are good, if not, any pot will do which is big enough to hold the wire basket of bottles. The milk or milk and deluent are placed in the bottles, which have been thoroughly cleaned with hot soda water, and an inch and one-half of water is placed in the bottom of the pot; when the water is boiling, the basket of bottles (without corks) is lowered into the pot and the same is covered. They are steamed thus for ten minutes to drive residual air out of the bottles. The pot is opened and each bottle is firmly corked and the pot covered, and steaming continued 45 minutes longer, when it may be considered completed in any weather. The basket of bottles are then placed in a shady cool place. If the family be intelligent and the bottles are not to be transported, the baked or even ordinary cotton may do as closure for the bottles.¹ Future efforts must also be made in order to obtain for the infant a milk which will be as free from contaminating elements as possible. A strict hygienic surveillance of dairies by competent persons, who can recognize diseased animals and milk, a strict accountability as to cleanliness of animals, utensils and hands. The rejection of receptacles which are unclean or composed of objectionable material will render milk sterilization in the household still more effective than it is at present.

¹ The fault to be found with the sterilizers now upon the market (Arnold and other patent cookers excepted) is that though they can all be used a la Soxhlet, there is not space enough between the bottom of the basket and that of the pot to allow of the use of the apparatus with steam alone, that is the introduction of 1½ inches of water and its steaming for one hour without the contact of the milk bottles and the water; this causing breakage. A firm in Baltimore is constructing a very cheap but complete sterilizer from my plan which will obviate these objections and be within the reach of the most modest household, per basket, bottles and corks complete.

INFANT DRESS.

Read in the Section of Diseases of Children, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY FRANK S. PARSONS, M.D.,
OF BOSTON, MASS.

LECTURER ON DISEASES OF CHILDREN, COLLEGE OF PHYSICIANS AND SURGEONS, BOSTON, MASS.

The average practitioner of medicine pays too little attention to the subject of infant dress. He goes about his daily duties, cares for and applies remedies to the sick infant, and, it may be, never gives a thought whether the child is properly clad, or if the material from which the clothes are made furnishes sufficient protection from the sudden atmospheric changes to which its delicate tissues are exposed. When he attends a confinement case, he seldom hints at any proper, hygienic method of arranging the baby's apparel, or dictates to the unscientific nurse what the infant shall wear. This leaves the subject to the mother, who, in the majority of cases, ignorantly binds the infant hand and foot, so that there is interference with the proper development of its muscles. Then, as the child struggles and cries for freedom, it is doomed to the conventional dose of peppermint or paregoric.

Scarcely can any one find in our text-books more than a passing remark on the hygiene of infant dress; in fact, it seems to be thought quite out of the province of medicine, and nurses become indignant when a physician attempts to suggest that he knows more about the needs of a child than they. Few good physicians doubt that the average infant is unwisely clad at the present day. It is bound too tightly, clothed too heavily, especially about the waist, and the style of garments renders the free use of its limbs practically impossible.

Let us see how the average newborn child of to-day is dressed. The baby being washed, the navel string is wrapped in a bit of linen, often well greased, and a flannel binder, extending from nipples to hips, is tightly wound around the body two or three times, and secured with four safety pins; the objects being to keep the abdomen warm, and prevent hernia when the child cries or strains.

Let us pause here a moment, and consider this binder. The Creator made the abdominal walls of a child elastic for a purpose, namely, to expand and protect vital organs when the little one cries, coughs or strains. If let alone, does it usually rupture? No. In crying or straining, the walls distend evenly in all directions, thus protecting the feebler portions, where hernia is apt to occur.

The binder prevents this even distribution of force, hence, the whole energy of the straining comes on certain parts of the walls that are weaker, and which, unfortunately, the binder

does not protect, and hernia is the result. It is the bandaged baby that becomes ruptured.

Now, suppose the binder is used for warmth alone, and is applied loosely, what happens? We undress our infant to find the binder up under the arm-pits, and the abdomen exposed. I have yet to see the necessity for any binder at all, unless to retain the dressing about the navel, and that only for a few days.

The best dressing for the navel, I think, is a simple pad of dry, antiseptic, absorbent cotton, wrapped about the cord, and left secured with a turn of a roller bandage, or a piece of adhesive plaster.

The next article of apparel is the shirt, made of all sorts of material; all wool, cotton and wool, silk, silk and wool, flannel; and I have even seen one made of linen, the coldest of goods, and starched stiff at that, keeping the baby fretting.

Then comes the pinning blanket, a long wool garment with a stout band, often of cotton. This is pinned snugly around the body up under the arm-pits, so snugly, in fact, that it materially interferes with the free expansion of the chest walls. One side is folded over one limb, and one over the other, and the bottom turned up and pinned, thus the infant is unable to move a limb. When a change of diapers is desired, the blanket is unfolded, exposing the child from foot to abdomen.

Now, a baby so exposed to varying degrees of temperature, and especially if overheated or perspiring, offers a factor in the etiology of any acute disease.

Next comes the skirt, with the same objections as the pinning blanket, tightness and inelasticity about the chest walls. This serves to increase the bulk and weight of clothing around the body of the infant, leaving the shoulders comparatively unprotected by only the light shirt and thin muslin slip, the last garment to be added.

Such is the dress of the average infant of today, and I ask, is it not time for us, as physicians, to give more thought to this subject, and instill, if possible, more hygienic and practical methods of dressing young children, to the minds of our respective communities?

The problem before us to solve, is to find something that will allow freedom of muscular movements, and having simplicity, will furnish warmth and protection.

First, let us consider the material to be worn next the skin for young infants. Of course this largely depends upon the financial condition of the parties interested, but the texture should be soft, non-irritating in character, warm, and as light in weight as latitude and climatic conditions will allow. Quality should take the place of quantity in baby clothes.

Then, too, we have the various infantile consti-

tutions to adapt our suitings to, because sickly infants, or those susceptible to colds from atmospheric changes, need greater protection than the robust and healthy. For those that can afford a dollar a yard, or more, the silk and wool flannel furnishes as complete protection as any material, and is, perhaps, the best goods to be worn next the skin; care, however, should be taken in washing it, as well as all other woollen goods. All wool materials are rather harsh and irritating to an infant. For the middle and lower classes there is nothing better than canton flannel; it is soft, warm, shrinks little, and can be obtained in various grades of quality, from 12½ cents to 50 cents a yard. For sickly children, an eider-down flannel is an excellent protective.

*Whole of undergarment
front view*

The infant dress I have to propose consists of an under-garment, covering the body from neck to feet; a skirt, supported from the shoulders; and a flannel slip in the colder months, or a muslin in the warmer, for an outside dress. There is no necessity for binder, socks or pinning blanket. I have for some time entertained the thought of reducing the size of the ordinary shirt and drawers pattern of nightgowns, worn by older children, to fit the average infant of two months, thereby allowing for the largest newborn child, or for the growth of the average baby to two months.

The development of this thought is the undergarment here exhibited. One modification I found by experience was necessary, namely: the

drawers should be made to separate from the shirt, if I wanted to make the changing of diapers easy, and avoid the washing of a whole garment where one part only was soiled. The under-garment can be made by any seamstress,

Flannel skirt

to cost as little, or much, as the quality of goods used requires, and as prettily as the style of garment or fancy of the mother permits. It consists of a shirt made with sleeves, opening in the back and reaching from neck to hips, long enough

Back of shirt

to meet the growth of the baby by simply altering the four buttons at the waist, to which the drawers are attached. This allows the whole garment to be supported from the shoulders.

Two buttons at the back opening of the shirt

are sufficient, a tie-string in the neck taking the place of the third. Lace may be put about the neck and sleeves. The drawers are made with flaps, as in the ordinary children's style, loose enough in the seat to allow for diapers. It is easier to unbutton four buttons, turn down the flaps and change diapers, than to unfold and unpin a pinning blanket, and in this suit all undue exposure of the limbs is prevented. The legs of the drawers are made to cover the feet, so that socks are unnecessary. It is intended to cover the under-garment with a simple skirt of good flannel, supported by shoulder bands, and reaching 5 inches below the feet, and over this a light flannel wrapper or muslin slip.

Thus the infant is clothed as prettily as the mother desires to make the suit, and as loosely, evenly and warmly as the interests of its own health require.

1438 Dorchester Ave.

"TETANUS NEONATORUM."

Read before the Section of Diseases of Children, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY B. A. WADDINGTON, M.D.,
OF SALEM, N. J.

I have seen in a practice of over twenty-six years eight cases of "Trismus Neonatorum;" of these six have been fatal in their termination, two have recovered.

I believe it to be of parasitic origin, the micro-organism most likely a "coccus." I do not say that it never occurs in the lying-in room of the cleanly with proper aseptic surroundings, but know that in all the cases I have seen the environment has been one of filth and squalor. My experience shows that more cases occur among the negroes than among the whites. Of the eight cases seen seven were negro children and one white child.

In the six fatal cases I resorted to the usual remedies: Calabar and chloral hydrate internally, chloroform by inhalation, ice to spine, Mariou Sims' procedure of manipulation of occipital and parietal bones to relieve pressure upon medulla oblongata or cerebellum, but all of no avail, the little ones died. But I now believe with proper aseptic and antiseptic treatment, there should seldom, if ever, be seen a case of "Tetanus Neonatorum."

In support of this theory, will report my two cases of recovery, with treatment:

Case 1.—Was called to see child (colored), at 12 M., January 10th, 1889, six days after its birth. Upon opening the door of the room in which the child was lying, a tetanic spasm was induced, lasting about three minutes, trismus marked, deglutition impossible, oposthotonos well defined, temperature 110.05F. Upon examination of ab-

domen found that the cord had sloughed off, leaving a nasty cauliflower excrescence exuding an ichorous discharge. Had the parts thoroughly cleansed with beta-naphthol solution and applied iodoform dressing, ordered internally one grain beta-naphthol and one grain chloral hydrate every hour, found no overlapping of occipital or parietal bones. Remained in the house about two hours, during which time the child had ten decided convulsions, ordered remedies continued and dressing changed at bedtime. Saw patient at noon the following day, found him sleeping quietly, had had ten or twelve light fits, the mother said, since I had been there, had made several futile efforts to get hold of nipple, had succeeded about an hour before my arrival, nursed freely and went to sleep. Ordered same doses of naphthol and chloral at two hours' interval and reapplied dressing to navel. Saw patient again at 4 P. M. next day, free from convulsions and all bad symptoms.

Case 2.—On March 3d, 1891, was called to see Mrs. —, the wife of a junk dealer, whom I had put to bed in labor ten days previous, and delivered of a healthy male child. She was suffering from a slight hemicrania, for which I prescribed, and was about leaving the room when she called my attention to the baby. She said that through the night he had tried to nurse but seemed unable to take hold of the nipple, but that she believed that he had three or four light fits.

I asked to see his abdomen, and while the mother was unpinning the bandage a marked and decided tetanic convulsion occurred, trismus, sardonic countenance and the most pronounced opisthotonos I have ever seen in a baby. Found the navel in a filthy condition, protruding granulations and foetid discharge. Ordered at once the thorough cleansing of the parts, syringing with peroxide of hydrogen and dressing with beta-naphthol; while this was being done the child had a number of convulsions, the least noise or draught being sufficient to produce one. Ordered beta-naphthol in one grain doses every half hour, and chloral hydrate, one grain doses every hour. This was at 9 P. M. Saw patient again at 12 M. the day following, symptoms greatly improved, had taken the breast once, the spasms were further apart and less violent, had slept considerably, ordered remedies continued but at further intervals. Saw child again next day at 3 P. M., all trismus gone, able to nurse freely, had had but two light spasms since I saw him last, navel quite healthy in appearance, and all foetor gone, continued the washing with peroxide and the dressing of beta-naphthol and internal remedies every three hours. Saw child next day at 10 A. M., well. Saw him again yesterday, still well.

THE EPIDEMICS OF INFLUENZA OF 1890 AND 1891 IN CHICAGO.

Read at the Congress of American Physicians and Surgeons, before the American Climatological Association, Washington, D. C., September, 1891.

BY E. FLETCHER INGALS, M.D.,
OF CHICAGO, ILL.

The epidemics occurring in Chicago the last winter and the preceding year differed from each other considerably in their effects upon the respiratory and digestive organs and the nervous system.

In 1890 the disease made its appearance about the first of January, but in 1891 not until nearly the first of March.

Persons of every class, all ages and either sex were attacked, but, as indicated by the observation of Dr. J. Suydam Knox¹, children suffered from it much less than adults; however, Dr. Charles Warrington Earle² saw many cases in children whom he thought experienced the same symptoms as adults. From my own observation, it appears that children were much less frequently affected than those of more advanced years.

The exact period at which the influenza first showed itself cannot be determined. Four or five weeks preceding the actual beginning of the epidemic, many patients suffered from acute rhinitis and sore throat, which were often termed influenza, though they did not appear different nor much more frequent than the colds which prevail in ordinary years.

However, during this same time, there occasionally occurred cases presenting the peculiar symptoms of sudden fever, malaise, great prostration and aching of the muscles, which have been so noticeable during the two epidemics. These isolated cases presented all the characteristics of influenza, and doubtless were of that nature; and it is probable that the peculiar condition or conditions causing them had more or less to do with some of the cases of acute rhinitis and sore throat just referred to.

The statistics of the Chicago Board of Health show that in 1890 there were 64 deaths in January from influenza, 37 in February, and 7 in March; and that in 1891 there were 4 in January, 6 in February, and 155 in March.

These, however, cannot be taken as accurate indications of the prevalence of the disease, for the returns are made by practitioners of all kinds, many of whom, during the reign of the epidemic, in order to retain the good-will of their patrons, found it expedient to confirm the diagnosis of "La Grippe" which had already been made by the patient or his friends. However, in these same months there were a larger number of deaths from pneumonia, very many of which were due to the influenza as a primary or com-

¹ Chicago Medical Recorder, p. 46.

² Ibid. p. 462.

plicating factor, and the prevalence of inflammation of the lungs, as pointed out by Dr. N. S. Davis, Sr., may fairly be taken as an indication of the extent and virulence of the epidemic.

In 1889, the year preceding the first occurrence of the epidemic, which was an average winter, there were recorded 384 deaths from pneumonia during the first three months; 128 in January; 111 in February, and 145 in March.

In 1890, the first year of the epidemic, during the same period there were 1,096 deaths from pneumonia, and in 1891, the same period, 1,233, of which 280 were in January, 233 in February, and 720 in March. The greater development of nervous diseases, as shown by Dr. Archibald Church,³ is also to some degree an indication of the extent of the epidemic.

As the character of the disease became pronounced, its accession was usually marked by a mild degree of inflammation of the mucous membranes, with lassitude, weariness, pain in the muscles, more or less distinct chill, and fever, ranging from 102 to 105° F. The pain was usually of a neuralgic character, and frequently disappeared within one or two days. In some instances, the mucous membrane of the eye and ear, in others of the respiratory passages or digestive organs, and in still others of the urinary tract, were most affected.

Dr. F. C. Hotz⁴ observed a large increase in the number of cases of conjunctivitis, both in dispensary and private practice, though there was nothing peculiar about the inflammation. More frequently he noticed inflammation of the cornea, ushered in by symptoms of acute irritation similar to those caused by a foreign substance under the conjunctiva.

These were always confined to one side, and were of two types; in one there was a zigzag line of superficial ulceration beginning at some point on the border of the cornea, and traveling toward the center, always confined to the surface layer of the corneal epithelium. In the other the surface of the cornea showed no disturbance, being smooth and brilliant, but on close examination by focal illumination, small, round, grayish spots were found located in the deeper layer of epithelium. In these latter cases, the pain and sensitiveness of the eyes, the quick reaction to the slightest touch, and increased secretion of tears, were very marked. These were easily mistaken for simple conjunctivitis if the cornea was not brilliantly illuminated by focal light. In these the congestion of the conjunctiva was pronounced, but did not show that dense red zone around the cornea usually characteristic of the inflammation of that tissue. The superficial ulceration recovered quickly, but the latter variety was of slow progress, and two months was the shortest period in which the eye recovered its normal con-

dition, though the ultimate prognosis was good in both varieties.

In the treatment of these cases, cocaine was the only local remedy which gave even temporary relief. Mydriatics seemed to act indifferently, or even to aggravate the irritation. Quinine internally had a decidedly beneficial effect on the neuralgic symptoms.

He observed numerous cases of inflammation of the middle ear, some of mild form, causing the patient but little pain or inconvenience, except a feeling of fullness in the ear, tinnitus or a buzzing sound, with slight deafness.

In others the inflammation was more severe, attended by rapid secretion of fluid, deep congestion, and marked bulging of the drum-head, with violent neuralgic pain in the ear, radiating over the side of the head. In these the hearing was speedily lost, and sometimes the drum membrane was perforated within the short space of twelve hours. The pain, which was of a severe form, did not usually, as in ordinary cases, subside with discharge of the secretion from the middle ear, but often continued for some time afterward. These cases were unilateral.

As a rule, the prognosis was good, no matter how severe the symptoms, and in most cases there was speedy recovery, but in a few the mastoid cells became involved.

He relied upon quinine internally to relieve the neuralgic symptoms, and recommended mild local applications, under which he had observed the quickest recovery.

Instillations of warm solutions of boric acid, with cocaine, and the occasional use of the Eustachian catheter for relieving the middle ear and tube of accumulated mucous, constituted the main local treatment.

Dr. Church⁵ believes that there was a well-marked variety of influenza properly denominated "nervous," which was indicated by the almost instantaneous prostration after the onset; the disproportionate asthenia during its course; the severe rachialgia, neuralgia, headache and sleeplessness, and the subsequent long, persistent neurasthenic state.

He believes the infection of influenza had a marked action upon the nervous system, giving rise to immediate acute manifestations, or to remote and persistent conditions; and that in those predisposed to la grippe, it was competent to cause marked excitement or great depression of the motor, sensory and mental apparatus.

During the progress of the epidemic, we observed frequent cases of this variety of the infection, indicated by pain, nervous prostration, local sweating, convulsions, coma, delirium and mania. During the prevalence of the epidemic, the deaths from nervous diseases were more than double the

³ Ibid, p. 418.

⁴ Ibid, p. 413.

⁵ Loc. cit.

number returned for the similar periods in other years.

The first epidemic was characterized prominently by rheumatoid and muscular pains, sometimes followed by articular rheumatism, and the last epidemic more by disturbance of the digestive organs.

The epidemic of the past winter has been followed by a widespread outbreak of typhoid fever, which, according to Dr. William E. Quine,⁶ has rarely, if ever, been equaled for the season of the year in this or any other section of the country; while in 1890, consecutively to the epidemic or concurrent with it, cerebro-spinal meningitis was extremely common.

Dr. J. H. Hollister⁷ has observed, as a prominent feature of the last epidemic, a form of continued fever, running from five to fifteen days, with high temperature and without intermissions, usually termed typhoid, but differing from it in that the specific ulcers of the glands and the characteristic stages and symptoms of typhoid fever were absent.

The effects of the disease upon the respiratory mucous membrane occurring under my observation did not differ materially in the two epidemics. There appears to have been some difference in the type of pneumonia, that of 1890 being more commonly of a catarrhal character, or broncho-pneumonia, and that of 1891, more frequently than in the former epidemic, of a croupous character. From my own research, I would conclude that during the past winter the tendency to the development of inflammations of the pleura has been much more pronounced than during the preceding winter. Many cases appeared peculiarly liable to terminate in suppuration. This view differs from the impressions of Quine,⁸ who thought the suppurative process more common in the epidemic of 1890.

The attack of influenza was usually ushered in by a mild degree of inflammation of the conjunctiva, Schneiderian membrane and the fauces, characterized by lachrymation, profuse watery discharge from the nares, swelling of the turbinated bodies, and more or less congestion of the mucous membrane of the nasal cavities, with more marked congestion and soreness of the fauces. However, the inflammation in any of these localities was usually comparatively slight—much less than ordinarily anticipated in influenza; indeed, even less than frequently attends ordinary cold. In such cases, in the course of thirty-six to forty-eight hours, the disease generally progressed to the larynx, where it was characterized by hoarseness and a hacking, annoying cough. After three or four days, all evidence of the attack frequently subsided. This was a most common site of the disease in both epidemics. Next in frequency was one in which

the trachea was chiefly involved; indeed, this seemed to me the most frequent of all where the patient was ill enough to consult a physician. The tracheitis was usually preceded by either rhinitis, pharyngitis, or laryngitis, but not infrequently was developed soon after the first symptoms of the attack, particularly without the intervention of inflammation of the upper air passages. It was usually attended with a most persistent tickling sensation in the trachea, which would provoke frequent, spasmodic coughs, generally attended, after thirty-six to forty-eight hours, with free expectoration. After four or five days, the sputa became of a thick, mucopurulent character, and often quite offensive to the patient. Such attacks, as a rule, were more protracted than those of the upper portions of the air tract, and often extended over three or four weeks.

Not uncommonly, in these cases, two months elapsed before the cough entirely subsided, and even then, on the occurrence of the slightest cold, the patient frequently complained of the same tickling sensation in the throat and irritating cough. Simple bronchitis, characterized by frequent spasmodic cough, and more or less profuse expectoration, was observed in a considerable number of cases, usually associated with one or other of the affections already mentioned, but occasionally independent. This, when uncomplicated, was not, as a rule, so obstinate as the tracheitis; however, in some instances, convalescence was delayed for several weeks, and in not a few cases the inflammation extended to the capillary bronchial tubes, and true catarrhal pneumonia was developed, which proved a most serious complication, and in not a few instances a fatal malady.

The majority of cases of pneumonia growing out of influenza were of the catarrhal variety, but it appeared to me that more were of this type in 1890 than during the past winter, when croupous pneumonia was peculiarly prevalent; the latter has usually run very much the course of ordinary croupous pneumonia, except that the patient has generally been more prostrated, and convalescence has been longer delayed. Pleuropneumonia has also been especially frequent, and uncommonly disastrous.

Cardiac symptoms, as irregularity, intermittence of the pulse, which was usually rapid but occasionally slower than normal, were frequently noted.

Dr. Quine⁹ had occasionally observed individuals who suffered from the grippe in 1890, still presenting a pulse rate varying from 40 to 60 beats per minute, accompanied by an enfeebled general condition, and with a strong tendency to syncope. Some cases of well-marked angina pectoris were developed during the epidemic, appa-

⁶ Loc. cit. ⁷ Ibid, p. 460. ⁸ Ibid, p. 459.

⁹ Loc. cit.

rently as the result of the influenza. Undoubtedly the cardiac complications frequently resulted from a rheumatism which was associated with the influenza, but most cases were apparently of nervous origin, and in some myocarditis or fatty degeneration of the organ appeared due to the specific effects of the morbid agent causing the epidemic, independently of rheumatism or other diseases in which the heart is secondarily involved.

Renal affections were frequently observed by Dr. I. N. Danforth¹⁰ as the result of the influenza, which appeared to induce, first, hyperæmia more constant and intense than provoked by other acute febrile diseases; second, a catarrhal nephritis; and third, a croupous nephritis, as demonstrated by an increased quantity of albumin, and the presence of true hyaline casts.

The essential points in the diagnosis of influenza implicating more particularly the respiratory organs, as we observed it, were the sudden accession of fever, with headache and excessive aching of the back and limbs, peculiar prostration, and the symptoms and signs of inflammation of the mucous membrane. It was distinguished from ordinary acute inflammation of the respiratory mucous membrane by the history and physical examination. Acute follicular tonsillitis often gives almost precisely the same symptoms as influenza, and can only be distinguished from the latter by an examination of the throat.

Laryngitis, tracheitis, or bronchitis due to the epidemic, could only be distinguished by the history, the excessive fever, and by the unusual pain which attended the attack of influenza.

The prognosis of influenza has been considered so favorable that the laity, and even physicians, at first considered it a laughing matter; and it is true that the majority of cases recover after a short time, even without medical care. But many cases terminated fatally, especially when occurring in the aged or infirm, and the large mortality from other inflammatory diseases, especially of the respiratory organs, and of the gastro intestinal tract, was undoubtedly largely due to the influenza. In a light attack, two or three days were generally sufficient to establish convalescence, and many patients continued their avocations, in spite of the discomfort caused by fever and nervous prostration. Even when the trachea and bronchial tubes were involved, three or four days were usually all the patient allowed before he considered it necessary to be again about his business. The prostration, however, entailed by the attack, usually continued from one to two or three weeks. Either of the forms of pneumonia growing out of the influenza generally lasted from 50 to 100 per cent. longer than attacks of the disease without the epidemic influence, and the fatal cases were much more common.

Patients who suffered from pneumonia, and even those who had comparatively mild attacks of tracheitis, or bronchitis, were often left in a depressed condition, which rendered them peculiarly prone to ultimate development of tuberculosis, and preëxisting phthisis was usually greatly aggravated, and its progress accelerated by the influenza.

I think I am perfectly safe in saying that during the past year, hardly a week has elapsed that I have not seen some case of phthisis directly attributable to this disease, and serious affections of the heart have not been infrequent.

Our treatment of these cases has not been essentially different from that of inflammatory affections of the same part occurring independently of the epidemic influence. However, careful attention to the nutrition, ferruginous and bitter tonics, especially strychnia, have been demanded more imperatively than in simple inflammations, and ultimately a change of climate has been more often required.

70 State St., Chicago.

CURABILITY OF CONSUMPTION.

BY CHARLES W. DULLES, M.D.,

PHYSICIAN TO RUSH HOSPITAL FOR CONSUMPTION; LECTURER ON DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC.

About 200 years ago (in 1672), Sir Thomas Browne, the author of that famous book, the *Religio Medici*—which every physician ought to read—wrote his almost equally famous "Letter to a Friend upon Occasion of the Death of his Intimate Friend." In this letter there is much curious and interesting writing in regard to consumption, to which disease the subject of it fell a victim. Of him Sir Thomas Browne says that he is "by this time no Puny among the mighty Nations of the Dead; for tho he left this World not very many days past, yet every hour, you know, largely addeth unto that dark Society; and considering the incessant Mortality of Mankind, you cannot conceive there dieth in the whole Earth so few as a thousand an hour."

He describes, in like quaint terms, the symptoms of consumption and the signs of approaching death, and reflects the common opinion as to its mortal character. Once only does he speak of recovery from the disease, when he says: "Monsters but seldom happen, Miracles more rarely, in Physick. Angelus Victorius gives a serious Account of a Consumptive, Hectical, Pthysical Woman, who was suddenly cured by the Intercession of Ignatius."

This view that consumption is almost necessarily fatal has prevailed in and out of the medical profession, and the idea that consumption is incurable is deeply rooted in most men's minds. Of late this idea has undergone some modifica-

¹⁰ Ibid, p. 428.

tion, and careful observers believe—what experience confirms—that consumption is curable. This belief has not yet extended as far as it should for the good of our fellow-men; but it is moving on, and we may hope it will before long do more than it has done thus far to relieve the dark and despondent notions in regard to a disease which is estimated to destroy about one-ninth of the human race.

So strongly, indeed, has the current of medical opinion set toward the belief that consumption can be cured, and that the recent advances in the management and treatment of it are but the earnest of what we may before long accomplish, that there is some risk of overlooking the fact that this belief and this hope are not new on the earth, and that long ago consumption was cured, and the principles that underlie the successful treatment of the disease were plainly enunciated or shrewdly indicated.

If we make due allowance for the uncertainty sometimes caused by the fact that most ancient medical writers used the words *phthisis* and *empyema* almost interchangeably, and that their descriptions do not always clearly show that the patients actually had what we now call *phthisis pulmonum*, it must still appear that even Hippocrates did not look upon the disease as incurable, and that from his time until the present, the possibility of recovery from consumption was fully recognized. Hippocrates, in his wonderful book on *Prognostics* (Sydenham Translation, vol. i, sec. 17, p. 248), describes the progress of what he calls “chronic empyemata,” and gives the indications of death, and also of recovery, in terms which leave little room to doubt he was speaking of consumption, or that he looked upon it as sometimes curable.

As one passes down from one to another of the older writers, the same idea can be traced, and cases of recovery may be found recorded—some of persons like Titus Pomponius Atticus, the friend of Cicero, who seems to have had warning in time of the possibilities of his long, small neck and his slender and weak body (Van Swieten's *Commentaries*, sec. 1198), and others like a patient of Hildanus (*Observ. Chirurg.*, Cent. III, Obs. 38), “a lady of quality” who was troubled for many years with a defluxion on her breast, and “at last spit up not only blood, but great quantities of purulent matter, and fell into a hectic, with a wasting of the body and loss of strength,” who yet, Hildanus says, was cured, and bore several children, although she had never been pregnant before (Van Swieten, sec. 1198).

One of the most interesting illustrations of the curability of consumption is found in the history of Dr. Christopher Bennet, who was born in 1617 and died in 1655. He was himself affected with *phthisis*, and succeeded in throwing it off, whereupon some of his friends persuaded him to write

a treatise on the subject. He yielded to their persuasions, and wrote his *Tabidorum Theatrum*, which was published in 1665, in London, with a preface by Martin Luellin. In this very rare book, Bennet has given much interesting and instructive matter; and it is no wonder—on the one hand—that he regarded his own disease as curable, nor—on the other—that a man capable of such shrewd observations should warn others against being deceived by false hopes. “A Physician,” he says, “ought not to be deceived by the first Flatteries of a Recovery, although there seem to be a perfect Restitution; for it is most safe to continue Means sometime after a Restoration of Health, for fear of a Relapse” (Transl., London, 1720, p. 174). He himself records the case of two patients “who threw up whole pieces of their lungs, which putrefied away by a lingering *phthisick*.” (Op. cit., p. 123.)

Van Swieten records (*Commentaries*, sec. 1209) a case of cure by Philip Ingrassias. The patient was a woman. “After a copious *hæmoptoe*, she had fallen into a consumption, and for several months afterward not only grew thin, but spit forth fetid pus. When this woman had taken decoctions of *lignum sanctum* (guaiac) for a month, she was so well recovered, that ten years after, when Ingrassias wrote the account, she was alive, and never had a relapse.”

If we come down to our own times or near them, we shall find that the curability of consumption has been recognized by almost all systematic writers.

The late Prof. George B. Wood, in his “Practice of Medicine,” says: “I am not one of those who believe that *phthisis* is in all cases necessarily fatal. On the contrary, I believe that, in one stage or another, it is occasionally cured, or at least ends in perfect recovery.” He cites several cases within his own observation which justify this opinion, among them that of his preceptor and friend, Dr. Joseph Parrish, who had symptoms of *phthisis* when young, and in whose lungs, after his death at an advanced age, cicatrices were found, which were obviously the remains of tuberculous cavities.

Dr. G. W. Hambleton, of London, in an able pamphlet on the suppression of consumption, published this year, declares that we now have it in our power to suppress consumption. And he says there is no essential reason why this should not be accomplished. “Man,” he says, “is not born to die from this disease, and, in fact, from four-fifths to six-sevenths of the race do not. We have unquestionable evidence that consumption has been completely recovered from, that a considerable reduction in its amount has been effected in some cases (for example, among prisoners), that it has been arrested for longer or shorter periods, and that persons with the signs of the disease have been able to completely es-

cape from it: consequently we must sooner or later ascertain the means by which that has been effected, and then we shall apply that knowledge to the prevention and cure of this disease."

Elsewhere in his pamphlet he says: "I have the right to express a clear and emphatic opinion on this subject; for I myself and my patients have unquestionably completely recovered from the disease. A great, a splendid, a noble victory over this disease lies in the hands of the profession. Shall we let doubt stand between us and its practical achievement?"

Those of us who have known medical men who are living witnesses to the curability of phthisis will not doubt the truth of what Dr. Hambleton says, or wonder at his earnestness in urging it upon his fellow practitioners.

More than this, we must some of us have some personal observation as to the curability of consumption, and I venture to say that there are but few medical men of much experience who could not cite cases in which the progress of this disease has been arrested, and it has been—using the expression in a just sense—cured.

If you were speaking I am sure you could report such observations, and my own convictions are founded in part on some such fortunate experiences. I have learned in practice what may be accomplished in the management of this dread disease, not only in its incipency, but also when it had made great progress. I have to day several patients going about in apparently good health and free from cough who a few years ago were unmistakably in the beginning of phthisis. No doubt you could say as much. But, to speak of cases much more advanced when they came under my care, I would cite one of a young man with hæmorrhages and free expectoration, whom Dr. Da Costa saw in consultation, and about whom he expressed the gravest prognosis. This young man got so well in about six months that he disdained restraint, despised caution, and brought on a second attack, of which he died. Another patient, almost as plainly doomed to speedy death, seemed well, when he took to drink and died one day after a profuse hæmorrhage, unpreceded by evidences of breaking down of the lung.

Another case was that of a young man who developed with relative rapidity the signs of consumption in 1884. In April he had consolidation in the upper part of the right lung. In June he had a slight hæmorrhage. In July he had a profuse one, followed by several slighter ones at intervals of a few days. During this time he had not much cough. By October he had a profuse greenish expectoration, which was brought up with violent coughing. During the summer his cough had been a source of great annoyance to the near inhabitants of the street on which he lived, and every one of his friends and neighbors

expected him to die soon. He became reduced almost to a skeleton, and in one of his hæmorrhages I was present and held a bowl into which he spit nearly a pint of blood. Notwithstanding all, he began to mend, and progressed until he had regained his usual weight, had no cough at all, ate well, slept well, and had no evidence of disease of any kind, except an insuperable laziness. In this state he lived for four years when, to complete his history, he took to drink and died, as his medical attendant, Dr. George Shoemaker, writes me, "of general breakdown from prolonged intemperance. The immediate difficulty was gastritis, some disease mitral, dilatation, poor compensation, and heart action greatly disordered. The last element caused him much physical and mental distress."

You will notice in this that there is not a word about phthisis. Experiences of this kind, I feel sure, are not peculiar to any practitioner, and the fact that I believe it is such as many other practitioners have had, encourages me to say that, as practitioners, we must not doubt that consumption is a curable disease, and we must not hesitate to encourage our patients to hope that they may be cured.

This is not the time for a discussion of the forms and stages of consumption in which the grounds for a hopeful prognosis are most or least firm. Nor can we now discuss the methods of treatment which give most promise of success. But one thing I think I may say, namely, that an early recognition of danger is usually an important condition of escape, and an early recognition of an incipient consumption is the most important step toward securing its recovery.

In closing, I would like to call attention to the fact that our country seems to be somewhat behind those of Europe in the careful and systematic study of this disease. If we are to contribute our share toward a better understanding of it, we must give more continuous study to it. A great aid to such study is found in certain large special hospitals for consumption in England and in Germany, where more or less conflicting views indeed prevail in regard to some questions of etiology and pathology, but where the most conscientious labor is devoted to investigating the principles of prophylaxis and treatment, and where great success is gained in both these directions.

In this connection I will quote Dr. Hambleton once more. He says: "It is of great importance that the consumptive patient should be placed under treatment as soon as possible, and that it be uninterruptedly continued until the recovery is complete. For this purpose we require hospitals and institutions placed in the most favorable conditions in the country and at the seaside, and I am sure the means will be gladly found for opening these institutions when once

their necessity and immense importance have been realized. With such institutions, so placed, and this system of treatment thoroughly and continuously carried out, I am certain we shall have reduced the mortality from consumption to truly insignificant proportions before the next century has escaped from its infancy."

One thing which encourages the belief that advances in the treatment of consumption and improved sanitary conditions may lead to its eventual disappearance from the world, is to be found in the fact that its ravages have been very materially lessened in the present century. Near its beginning, Dr. Thomas wrote, in his "Practice of Medicine," that the deaths in Great Britain each year were calculated at not less than 55,000 in a population of 11,000,000. This number of deaths has never been passed since then, and in 1888 it fell to 44,248, when the population of England was about 40,000,000, nearly four times as great as when Dr. Thomas wrote. This is a different experience from that of the last century, in which, as Dr. Thomas says, the mortality very considerably increased.

Dr. Flick, of Philadelphia, who has made a careful statistical study of the progress of consumption in England and Wales, has attributed the marked falling off in the death rate from this disease to the establishment and maintenance of special hospitals for the treatment of phthisis and its allied diseases. Such hospitals exist in large number (about forty) in England and Wales, and a certain number are in successful operation in Germany, while others are projected there.

There are already a number of sanatoria for consumptives in this country; but they come very far short of meeting the necessities of the people. In number they are too few, and in scope they are too limited.

The need of the moment, I believe, is a hospital for the careful and systematic study of consumption and its allied diseases—a *hospital*, not a sanitarium or a retreat, where the patients are regarded as incurable, and the duty of the physician is to gently smooth their pathway to the grave, but a hospital, where the study of the disease and of the best means to treat it shall engage the attention of a strong body of men of scientific mind and practical skill.

I am happy to be able to say to you that a hospital for consumption has been established in Philadelphia. This hospital is called the "Rush Hospital for Consumption and Allied Diseases." It has been named in honor of the great American physician who is as conspicuous in the history of medicine in this country as was Franklin in philosophy and political science. To Benjamin Rush this hospital will be, we may hope, a more enduring and more suitable monument than we could raise in brass or marble.

SOCIETY PROCEEDINGS.

American Surgical Association.

(Concluded from page 533.)

THURSDAY—EXECUTIVE SESSION.

The officers for the ensuing year are as follows: President, Dr. Phineas S. Conner, Cincinnati; First Vice-president, Dr. L. McLane Tiffany, Baltimore; Second Vice-President, Dr. Levi C. Lane, San Francisco, Cal.; Secretary, Dr. J. R. Weist, Richmond, Ind.; Recorder, Dr. J. Ewing Mears, Philadelphia; Treasurer, Dr. John B. Roberts, Philadelphia; Member of Council, Dr. Claudius H. Mastin, Mobile.

The committee recommended the following resolution, which was adopted:

Resolved, That the Association hereafter hold each triennial meeting at Washington, and that other annual meetings be held at such time and place as the Association may name.

It was decided to hold the next meeting in Boston, in June 1892.

The following were elected to membership: Dr. J. S. Wight, Brooklyn, N. Y.; Dr. E. W. Walker, Cincinnati, Ohio; Dr. George R. Fowler, Brooklyn, N. Y.

The following honorary members were elected: Mr. John Chiene, Edinburgh; Mr. Reginald Harrison, London; Mr. Thomas Bryant, London; Mr. Arthur Edward Durham, London.

THURSDAY SESSION.

DR. FREDERICK S. DENNIS, of New York, read a paper on

RECURRENCE OF CANCER OF THE BREAST.

Only those cases were included in which a microscopical examination of the tumor has been made; the necessity of an investigation of carcinoma of the breast is shown by the fact that in England alone 7,000 deaths occur annually from carcinoma, and a large proportion of them are cancer of the breast. It has been demonstrated that cancer is a disease which is slowly increasing in civilized nations. A study of the subject shows that there are 75 per cent. of recurrences. These cases include cases of incomplete operation, *i. e.*, when axilla has not been opened. In the primary growth at the beginning, the neoplasm is of local origin. Early and complete removal of the growth relieves the local disease, but the operation does not relieve the predisposition or susceptibility or the capability for the recurrence of the disease. It is possible that the capability is limited to certain extent.

The recurrence of carcinoma of the breast is influenced first by the period of time from the appearance of the growth to the date of the operation. In the cases of the author in which the cure had continued for three years or more, the tumors were removed on an average six months

from the date of their first recognition in the breast. In all cases of permanent cure, the axillary glands were not invaded.

Recurrence is influenced, second, by the extent to which infiltration has taken place by any one or all of the three well recognized ways of dissemination. When the tumor has existed long enough to show extension in these directions, the growth has been of long duration.

Third, recurrence is influenced by the radical character of the operation itself. Complete removal of the breast is essential. The method of Mr. Stiles of Edinburg, by which the tumor after removal is treated with dilute nitric acid in order to show whether or not the incisions have been made in healthy structure and all the diseased structure has been removed, was described. The reported mortality of the operation is high, but in the author's 71 cases there had been but one death and that was from continued bleeding in hæmophilia.

Fourth, recurrence is influenced by the histological character of the carcinoma itself. Where the structure differs slightly from the normal the clinical history is favorable. In none of these cases was there recurrence. Where there is great departure from the normal type, the clinical history is unfavorable. The more embryonic the structure the greater the chance of recurrence.

Fifth, the recurrence is influenced by the simultaneousness in both breasts. This occurs in five per cent. of the cases. These patients are very liable to recurrence.

Sixth, recurrence is influenced by the personal factors of the individual, such as age, sex, marriage, fecundity, sterility, pregnancy, traumatism, heredity, menstruation, metastasis, mental condition, locality, etc.

Seventy-one cases of carcinoma of breast which had been operated on were referred to. In one there had been death from hæmophilia. In nearly all the axilla was opened. The operation consisted of excision of the entire breast, with all contiguous skin, the para and peri-mammary, fatty areolar tissue, the pectoral glands, the pectoral fascia and also removal of the axillary glands and fatty axillary tissue. In some cases the supra clavicular glands were removed, and in one case excision of the ribs was done. The percentage of permanent cures amounted to 30 per cent. The other held that with early and radical operation, recurrence of carcinoma of the breast will be comparatively rare.

MR. THOMAS BRYANT, London, believed firmly in the local origin of carcinoma, although we must admit that there may be a predisposition on the part of the patient to the development of the disease. The disease should be treated at an early period, and this brings us to the question of diagnosis. Many cases do not come under observation until the disease is well advanced, because

the patient imagines that a disease unassociated with pain cannot be cancer. Where induration appears in a breast during the period of functional activity there may be some hesitation in the diagnosis, but in some thirty cases of this kind he had recommended immediate operation, and in all the cases, the disease was shown to be malignant. In none has recurrence taken place. When the disease has advanced somewhat further with dimpling and puckering of the skin and some immobility, we may get a good result by making a thorough operation. He had had some cases without recurrence for from five to twenty years. In the more advanced cases the surgeon should limit his operations to those in which there was a reasonable prospect of removing all the diseased structure. He does not remove the axillary glands in every case. If the glands be enlarged or the disease extend upward in that direction he removes the glands thoroughly; where the disease is quite local, and there is no evidence of axillary involvement, the axilla is not opened. In the atrophic form of cancer he thought it better not to interfere unless the tumor was giving rise to great inconvenience. Operation in these cases is often followed by a more rapid form of growth. Again in that form of cancer where the lymphatics can be traced distinctly, and the breast has a brawny feel—the lymphatic form of cancer—the surgeon does no good by interference.

SIR WILLIAM McCORMAC, London, thought that the axilla should be opened in operations for carcinoma of the breast for two reasons, viz.: an examination of 117 cases of cancer of the breast showed that in all but two there was axillary involvement, and second, in ninety per cent. of the recurrence the disease appears in the axilla.

DR. LEWIS S. PILCHER, Brooklyn, thought that the term "recurrence" was not applicable to many of these cases, and that in many the disease was simply a continuance of the former growth. If the case goes one year without the appearance of return of the disease, it may be considered that the disease has been removed, and if it appears later, it can be regarded as a recurrent, a renewed or a new attack of cancer. In every case of cancer there is a predisposition to the disease, and we should search for some agent to counteract this constitutional predisposition which we can use in addition to operative measures. Arsenic has for many years been used for this purpose. Dr. Wight of Brooklyn has suggested the use of carbonate of lime for the same purpose.

DR. L. McLANE TIFFANY, Baltimore, did not think that we could set any limit to the time of which recurrence might take place. He had had the disease return eight years after operation. He was a firm believer in the local origin of cancer. The date at which the disease is recog-

nized varies much. In some the disease comes before the surgeon shortly after its commencement, while in others the tumor has reached considerable size. The time at which the disease is discovered by the patient, bears no relation to the time of its commencement. Too much stress had not been laid on the necessity of thorough operation. In only two cases out of 80 operations for cancer of the breast had he found the axillary glands not enlarged. The pectoral fascia should be removed, and at times portions of the muscle should be cut away.

DR. KINGSTON, Montreal, believed that cancer was essentially a local disease. If we believe this operation should be done at as early a date as possible, the glands should be removed not only from the axilla, but from its neighborhood if they are enlarged, but this should not form a necessary part of the first operation. Such a procedure adds greatly to the discomfort and to the danger. Where there is the slightest suspicion of involvement of the glands, they should be removed. If there should be recurrence the operation should be repeated as often as circumstances seem to warrant.

DR. JOSEPH RANSOHOFF, Cincinnati, reported thirty cases of removal of the breast for cancer, without a death. He thought the danger of the operation was not materially increased by opening the axilla.

DR. C. B. NANCREDE, Ann Arbor, said with reference to the three year limit that this had been proven to exclude 98 per cent. of the recurrences. It is impossible to tell whether or not the axillary glands are involved without opening the axilla. Unless this is done the majority of the cases will be left unbenefited. He advised that the axilla be opened first and if the glands could not be removed to close the wound and not remove the breast.

DR. J. R. WEIST, Richmond, Ind., had operated fifty-five times for cancer of the breast and makes it a rule to open the axilla in every case.

DR. GEORGE W. GAY, Boston, felt that there was no such thing as a local origin of cancer as we have the local origin of a fatty tumor. When it can be shown that a cancer taken out will not return just as a fatty tumor when removed does not return, then we can prove the local origin of carcinoma.

DR. EDWARD M. MOORE, Rochester, always operates in as thorough a manner as possible. He always opens the axilla and did not think that it added to the risks of the operation. He did not agree with Mr. Bryant in regard to the atrophic cases in old individuals. In these he recommended operations considering recurrence very improbable. He reported one case living seventeen years after operation, and now seventy-nine years of age.

DR. C. B. PORTER, of Boston, then read a paper on

A CASE OF DIFFUSE FIBROMA WITH A TENDENCY
TO INTRACANALICULAR GROWTH OF
BOTH BREASTS.

Mrs. M., æt 37 years, resident of Nova Scotia, was admitted to the Massachusetts general hospital. Has had two children, the youngest ten years old. Three years ago she discovered a hard lump in the right breast which gradually increased in size. Three months later the left breast commenced to enlarge. The breasts continued to slowly enlarge until three months ago when a rapid increase took place and the breasts soon became burdensome by their size and weight. On examination she was found to be pale, emaciated, and with ovarian pains. Right breast, largest circumference 38 inches; length from chest wall to nipple 17 inches; circumference at base 23 inches. Left breast, largest circumference 28 inches, length from chest wall to nipple 14 inches; circumference at base 23 inches. Throughout both breasts were felt movable hardened masses of irregular outline, varying in size from an orange to a closed fist. It was decided to remove the left first. The breast was transfixed at the base with two skewers and constricted below this with a tightly drawn rubber tourniquet. The breast was then removed and but little blood lost. Three weeks later the right breast was removed. Twenty days after the second operation the patient was permitted to leave the hospital to visit friends, but instead she returned to her home, requiring a long sea journey. A week later she developed erysipelas. This had much improved in four days when she suddenly aborted a five months' fœtus.

The weight of the right breast after removal was 43 pounds, and that of the left 17 pounds, a total of 60 pounds. A resumé of the reported cases was added.

DR. J. M. BARTON, of Philadelphia, reported a similar case on which he had operated, and in which one breast was involved. Adjourned Thursday.

FRIDAY MORNING.

The committee to which was referred the suggestions in the President's address offered the following resolution, which was adopted:

Resolved, That the President appoint a committee with authority to confer with the friends and admirers of Professor S. D. Gross, and with the profession at large, for the initiation of a movement on the part of the Association, having for its object the erection of a monument to Dr. Gross in the City of Washington.

As the matter is an important one, the President stated that he would announce the committee in a few days.

DR. LEWIS A. STIMSON, of New York, read a paper on

TREATMENT OF FRACTURES INVOLVING THE ELBOW-JOINT.

The special interest of the subject arises from the frequency with which fractures of the lower end of the humerus are followed by more or less diminution of the function of the elbow-joint, and by deformity of the region or of the limb. The paper was devoted mainly to a consideration of the causes of these unfavorable results.

Causes of limitation of motion. Permanent stiffness after simple fracture is commonly due to change in the shape of the articular surfaces or in their relations to one another, that destroys the coincidence of the axis of curvature with that of motion; or to an overgrowth of bone upon the surface of the humerus, arresting the movement of the olecranon or coronoid process; or to more or less extensive ossification of the ligaments and capsule.

Overgrowth of bone from traumatism is more frequent in the young than in the adult. As limitation of motion may be caused by bony outgrowth from the humerus, itself the result of a persistent displacement of a fragment or of separation of the periosteum, the most efficient way to prevent it lies in an exact diagnosis and reduction of displacement, and in the avoidance of any subsequent irritation of the periosteum.

Limitation of motion from thickening of the capsule and periarticular tissues by the products of inflammation is, as a rule, a temporary condition. In the more permanent form, the lesions are more extensive, the soft tissues are torn, and a true cicatrix results. The thickened tissue may become ossified in whole or in part. This cause of limitation has been attributed, but improperly so, to prolonged immobilization, and has led to the practice of passive motion in the early stages with the object of preventing its occurrence. Observation and experiment have, however, shown that immobilization is not itself a cause of ankylosis, but that it is an efficient agent against inflammation, and that passive motion is powerless to prevent ankylosis when conditions contributory thereto are present. Passive motion, therefore, is either harmful or useless. The primary cause of the exudation and of the proliferation of connective tissue that are the anatomical obstacles to motion, is of course the original traumatism. The secondary cause is the following reaction. The only factor that can be increased or diminished by treatment is the second—that is, the inflammatory reaction. Rest is universally admitted to be the best antiphlogistic measure that can be applied to an inflamed joint. An important disadvantage of rest at once suggests itself, namely: that the torn tissues may unite with shortening. Both clinical observation and theoretical considerations indicate that passive motion in the early stage does not avoid this disadvantage, but actually in-

creases it. In the present state of our knowledge, it seems that a certain amount of limitation is unavoidable. Massage, however, hastens the absorption of exudation and the restoration of mobility, as does also permanent elevation or suspension of the limb. Reunion with shortening may be opposed by change in the attitude of the limb every few days. At a later period passive motion has its value, but in the early stages it is to be avoided.

In regard to deformity, reference was made to only one, that commonly known as the "gun stock" deformity, due to unreduced displacement of the internal or external condyle. In order to avoid this deformity, the displacement should be reduced by pressure upon the fragment or by abduction of the extended forearm until its outward deviation is equal to that of its fellow, and immobilization by dressings that will not reproduce the displacement.

Treatment.—The first element in the treatment is the reduction of the displacement. If necessary, an anæsthetic should be employed. In supra-condyloid fractures, permanent traction is usually necessary to overcome the displacing action of the flexors and extensors. This can be effected by vertical suspension of the limb, the patient being kept in bed, or by a weight suspended from the upper part of the flexed forearm while the patient is erect. The former method was recommended for the first fortnight of treatment, especially in compound fractures. Suspension is made by strips of adhesive plaster placed along the front and back of the forearm, and attached to the support of India rubber cords, or a weight and pulley. In simple fractures, the other method may be employed. The limb is encased in plaster of Paris with the elbow at a right angle, the wrist being placed in a sling, and a weight not exceeding 5 lbs. suspended from the elbow.

In inter-condyloid fractures with marked separation, there is no practicable means of surely maintaining reduction, and considerable limitation is to be expected. In these cases, a broad, heavy posterior splint, covering about two-thirds of the circumference of the limb, the elbow being at a right angle, was recommended.

In fracture of either condyle, the treatment is by a posterior rectangular splint, either metal or plaster. The forearm has been supported across the chest by a sling at the wrist. In some cases treatment in full extension has been employed. After this method has been employed for the first ten days or fortnight, recourse is had to the position with the elbow at a right angle.

Gentle massage will hasten convalescence. It may be advisable to change the position of the limb during treatment, and if great limitation is to be expected, that attitude should be given to the joint in which, if stiff, the usefulness of the limb will be greatest. In supra-condyloid and

intra-condyloid fractures, the splint should be worn six weeks, and in fractures of the condyles, for about four weeks. After removal of the splint, the arm should for a few days be supported in a sling. If necessary, passive motion may at this time be resorted to to increase the range of motion.

DR. N. P. DANDRIDGE, of Cincinnati, agreed with what had been said by the reader of the paper, and referred to two cases occurring under his observation. In one case of simple fracture from great violence in which non-union had occurred, the arm was treated in a position of almost complete extension. The second case was one in which after fracture at the elbow joint a projection of bone pressed upon the median nerve, causing severe pain and atrophy of the muscles in the distribution of the nerve. The case was seen three months after the accident. Removal of the bone was followed by relief of the pain and a gradual restoration of the function of the muscles.

DR. R. A. KINLOCH, of Charleston, thought that in simple fractures about the elbow, if seen early and the ordinary principles in regard to the treatment of fractures be applied, the result would be good. Probably in a large number of cases we must expect some restriction of movement. The most important element in the treatment is the proper reduction of the fragments. This should be done at once, an anæsthetic being employed if necessary. The proper reduction of the fragments is determined by testing the functions of the joint. The second indication is to retain the fragments in the proper position. If the case is treated with intelligence, it makes little difference what way the splint is applied, or whether it is treated in flexion. The position is to be determined largely by the peculiarities of the individual case. He was himself inclined to favor the extended position.

In regard to passive motion used early, he thought that it did more harm than good. If the parts have been properly reduced and held in position, and there is a danger of subsequent trouble, passive motion may begin in three or four weeks.

DR. E. M. MOORE, Rochester: In a fracture of the internal condyle the cause of the displacement is the flexor muscles, and to relax these muscles the arm is to be placed in the flexed position. In fractures of the external condyle he had also found this position the preferable one, for when the forearm is flexed the dense fascia on the front of the arm is rendered tense and acts as an efficient splint. He objected to the extended position entirely. He treats all fractures about the elbow joint, with the exception of fractures of the olecranon, in the rectangular position for the first ten days or two weeks. Lateral splints are used with the object of pressing the frag-

ments together. After the tenth day the fracture is dressed every other day, the angle of the splint being changed a little each time, so that the arm passes from almost complete flexion to almost complete extension. He had never had the slightest difficulty in any case since adopting this mode of treatment.

DR. JAMES M. CANN, Pittsburg, said that it was not always easy to determine the exact nature of these fractures about the elbow joint, even with the patient under the influence of an anæsthetic. While the patient is under the anæsthetic the preliminary dressing should be applied. He recommended the use of the internal angular splint, preferably that suggested by Dr. Packard. He did not favor the use of passive motion at an early stage. Passive motion should not be resorted to prior to the twentieth day.

DR. JOHN B. ROBERTS, Philadelphia, thought that the teaching advocated by some of the speakers was to a large extent dangerous and incorrect. That is, that injuries about the elbow joint should be treated in the flexed position. He believed that, except in unusual cases, these fractures should be treated in the extended position, according to the doctrine advocated by Dr. Allis. In this way the gun-stock deformity is avoided. He now approached fractures of the elbow with the same certainty of getting a good result as he did fractures of the lower end of the radius.

DR. S. H. WEEKS, Portland, dwelt upon the fact that all authorities, with few exceptions, advised the flexed position in the treatment of fractures about the elbow joint. Until there was more positive evidence of the value of the extended position he thought it better to continue to treat these fractures in the flexed position. He employed passive motion in a modified way. After two weeks' treatment the splints are removed and the joint moved gently but not sufficiently to cause pain. This simply alters the relations of the parts without doing any damage.

DR. L. McLANE TIFFANY, Baltimore, thought that as good results were reported from various dissimilar methods of treatment, we must conclude that the prognosis of elbow injuries depended more upon the patient than upon the surgeon. Fracture of the elbow is rare in adults and common in children, and in children, with reasonably good treatment, there should be a good result, and by the time adult age was reached the motion would be almost perfect. In the adult the prognosis is more grave. He had had good results both with the flexed and with the extended position. In compound fractures, the secret lies in the relief of tension, irrespective of the apparatus employed. Incision up and down the arm through the strong fascia should be made as freely as may be required.

ALBERT VANDERVEER, M.D., of Albany, read a paper on

RETRO-PERITONEAL TUMORS, THEIR ANATOMICAL RELATIONS, PATHOLOGY, DIAGNOSIS AND TREATMENT, WITH REPORT OF CASES.

As our experience in abdominal surgery increases we find that there are yet many problems that confront us, and of these problems there are none which requires more careful research and is capable of greater improvement both in operative management and in prognosis, than new growths arising from the retroperitoneal space. In order to bring this subject more fully to the attention of the association, the following cases are reported:

Case 1.—Miss S., æt. forty-two years, consulted the author in March, 1882, on account of a tumor located in the back. This was first noticed fifteen years previously. Examination showed a large tumor attached to the right side of the spine at the level of the first lumbar vertebra. It seemed attached to surrounding tissues of a smooth contour and hard to the touch. Operation was advised but declined. The tumor continued to increase in size until November, 1888, when she died from other causes. The autopsy showed the origin of the growth to be the connective tissue about the right kidney. It was encapsulated and could have been easily removed. It weighed eight pounds. The microscope revealed the presence of fat and myxomatous tissue with an abundant small round cell infiltration.

Case 2.—Mr. V., æt. 41 years, married, was first seen May 28th, 1889. Five years ago strained his back. The pain following this has not been relieved by any treatment. Three months ago he became worse, the abdomen began to enlarge. The pain was more severe. He lost appetite and flesh. The ankles became œdematous and a distressing cough developed. The urine was scanty and high colored, but free from albumen and casts. The abdomen was more prominent on the right side. Fluctuation could not be elicited but palpation gave an impression similar to that of a lipomatous tumor. On the right side there was flatness from the nipple to the crest of the ileum with the exception of a narrow space along the border of the ribs where there was a zone of resonance. The probability of the growth arising from the kidney was strong and an exploratory abdominal section advised.

This was done June 1, 1889, an incision five inches long being made over the external border of the right rectus muscle. The growth was reached and the capsule divided, but from its attachments it seemed futile to attempt its removal. The patient recovered from the operation and for a considerable period was relieved of pains. The growth continued to increase in size and the patient died October 21, 1889.

The tumor, which weighed fifty-six pounds, originated behind the peritoneum and was attached to the right kidney. The microscope showed it to be an adipose tumor presenting a condition of myxo-sarcoma with sarcomatous infiltration.

Case 3.—Mr. N., æt. thirty-nine, a brass worker by occupation, began to have vague abdominal symptoms late in the year 1888 with failure of flesh and strength. In June, 1889, he developed jaundice and a tumor was found in the left hypochondriac region and lumbar region. This was as large as a child's head. An exploratory operation was advised, but refused. It was believed that the growth was connected with the left kidney. The tumor continued to grow and in November, 1889, the patient died. The tumor was found to have sprung from the region of the left suprarenal capsule and involved it. It also surrounded the kidney. It weighed six and one-eighth pounds. The microscope showed an appearance similar to that in case two, but with a greater preponderance of sarcomatous and myxomatous elements.

A careful study of the reported cases and of the literature of the subject impresses one with the belief that the most frequent origin of these growths is in the connective tissue of the capsule of the kidney, and that the next most frequent seat is the supra-renal capsule. None of these tumors can be said to be absolutely benign, even those which are made up entirely of histological elements, such as lipoma fibroma, or myoma. While they show no great tendency to recurrence after complete removal, yet from the great size to which they develop and their tendency to undergo degenerative changes, they cannot be classed as innocent growths.

In many of the reported cases the origin is not stated, and indeed it would, from the subsequent changes in anatomical relations, seem quite impossible to determine the exact origin of many of the large retro-peritoneal growths. They almost always present themselves in the line of least resistance, that is anteriorly. A careful study of these tumors shows them to be of a mixed variety, containing both the elements of the lipoma and myxoma tissues which are histologically very closely associated. Fat is developed from embryonal mucin and in post-fœtal life occupies those spaces in the economy which later in the fœtus is of myxomatous elements. Doubtless many of these growths arise under suitable conditions. From congenital neoplasms these growths often become cystic and reach immense proportions. They often present a numerous round celled infiltration pointing to a sarcomatous element. Sarcoma, either in its typical form or in combination with other tissues, often occurs.

Diagnosis.—There is not a single symptom

that is pathogenic and the diagnosis is more dependent upon the process of exclusion. Tumors of the other abdominal and pelvic organs, as well as aneurisms and tumors of the abdominal wall, must be excluded. As already stated many of these tumors have their origin in the capsule of the kidney or the connective tissue surrounding it. These present, in their earlier stages at least, physical signs differing in no respect from tumors of the nephritic parenchyma. In none of the cases reported has renal hæmorrhage or albuminuria, with or without casts, occurred, conditions which are the rule with tumors of the parenchyma of the kidney. A valuable adjunct in the diagnosis consists in noting the relation of the tumor to the intestinal tube as shown by the insufflation of hydrogen gas.

Prognosis.—Without operative interference there is but one termination. The rapidity with which the fatal result is reached varies with the character of the growth. The mean duration of life after the discovery of tumor is about nine months. Operative treatment offers much promise; the immediate mortality of the operation is great, yet from the hopelessness of the condition it is to be urged with great earnestness.

In operations for the removal of retro-peritoneal growths, the choice of incision will usually fall in the line of the linea semilunaris. By the separation of the peritoneum from the internal border of the tumor, it may be attached to the internal border of the abdominal wound, making the whole field of operation extra-peritoneal, the incision of the posterior fold of the peritoneum should be external to the attachment of the mesentery of the colon, although not absolutely necessary. In the removal of the growth by enucleation, care should be taken to determine the source of the blood supply and the relation of the great vessels. There are likely to be large thin-walled veins deep in the wound, requiring ligature. At times it will be found necessary to remove the kidney with the tumor. As in all abdominal work the operator should be prepared for any and every complication. After enucleation the cavity must be thoroughly drained. The after treatment is the same as in all other severe abdominal sections.

Like all other conditions in surgery, there is certainly a better understanding of these cases going on. A more correct and early diagnosis, as is the case in all that pertains to medicine and surgery, will surely bring a larger percentage of recoveries.

These are purely surgical cases. No medicines, no mineral waters or baths, electricity or other lines of therapeutics, having as yet been of any service. To the paper was appended a complete bibliography of retro-peritoneal new growths.

DEFOREST WILLARD, M.D., of Philadelphia, read a paper on

INTRA-THORACIC SURGERY. BRONCHOTOMY THROUGH THE CHEST WALLS FOR FOREIGN BODIES IMPACTED IN THE BRONCHUS.

DR. WILLARD gave the results of a number of experiments on dogs, in which an opening was made in the chest walls, one or more ribs excised, and the bronchus thus reached, either anteriorly or posteriorly. The operations were all fatal.

The following conclusions were presented:

1. In dogs, the bronchus can be reached either anteriorly or posteriorly through the chest walls, but the anatomical position is in such close proximity to large and important structures, that safe incision is a matter of extreme difficulty and danger.

2. Bronchotomy through the walls of the thorax is an operation attended with great shock from collapse of the lungs, and until the technique is farther advanced, is liable to result in immediate death.

3. Collapse of the lung is more serious in a healthy organ than in one physically crippled by disease.

4. The serious inherent difficulties are shock, suffocation from lung collapse, enormous risks of hæmorrhage from pulmonary vessels, injury of or interference with the pneumogastric nerve, great and fatal delays, owing to the exaggerated movement of the root of the lung caused by the excessive dyspnœa.

5. Closure of the bronchial slit is slow and dangerous. To leave it open causes increasing pneumothorax, by its valve action, and also permits the entrance of septic air into the pleural cavity.

6. Although a foreign body can be reached by this route, yet removal is hazardous. To secure a subsequent complete cure seems, in the present state of knowledge, very problematical.

7. When the presence of a foreign body in the bronchus is definitely determined, and primary voluntary expulsion has not been accomplished, there is great danger in permitting it to remain, even though it may but partially obstruct the tube. The risks both of immediate and of subsequent inflammation are serious.

8. Low tracheotomy is then advisable when the presence of a foreign body is certain. It adds but little to the risks, and affords easier escape for the object, even when extraction is not feasible.

9. *Subsequent dangers arise from severe and prolonged instrumentation; not from tracheotomy.*

10. Voluntary expulsion is more probable after than before tracheotomy.

11. Tracheotomy is permissible even after an object has been long in position, unless serious lung changes have resulted.

12. The question of tracheotomy will depend

largely upon the form, size and character of the foreign body.

13. The term bronchotomy should be limited to an opening of the bronchus, and should not be employed to designate higher operations.

14. The risks from thoracotomy and bronchotomy following unsuccessful tracheotomy are much greater than the dangers incurred by permitting the foreign body to remain.

DR. J. R. WEIST, of Richmond, said that from a study of one thousand cases in which a foreign body was impacted into a bronchus, he had reached the conclusion that the chances of the patient were better if left alone than if an operation of what was formerly called bronchotomy was done.

DR. S. H. WEEKS, of Portland, thought that in these cases tracheotomy should be performed, as this affords a chance of reaching the foreign body, and also offers a chance for the spontaneous expulsion of the body. It occasionally happens that the body is forced up against the vocal cords and then falls back, or else suffocates the patient before relief could be afforded. He reported the case of a child of ten years, who had so gotten into the trachea a screw cap that was used to close a pocket flask. It had been there several days before the patient came under observation. It was decided to open the trachea. This was done, and the patient suspended, but the foreign body did not escape. The patient was then placed in the horizontal position and the attempt made to remove the cap with forceps. It could be felt, but not grasped. After working unsuccessfully for some time, the patient was again suspended and the attempt with the forceps renewed, and at once the body was grasped and removed. The patient made a perfect recovery.

DR. KINGSTOWN, of Montreal, reported a case in which he had removed an artificial incisor tooth with its attachments from the trachea where it had remained for three months. The operation necessitated prolonged manipulation but was followed by no bad results.

DR. HOWARD MARSH, England, thought that on account of the danger of leaving the foreign body in the bronchus, the uncertainty in regard to the possibility of removal until the attempt is made, and the safety of tracheotomy, the operation should be performed. The operation should be performed in all these cases as it gives the patient a chance where otherwise he perhaps has none.

MR. ARTHUR EDWARD DURHAM, of London, agreed with the author of the paper that the operation through the chest wall was a dangerous and doubtful procedure. The more he saw of these cases the more satisfied was he that the proper thing to do where there is clear evidence that a foreign body is impacted in the bronchus, is to open the trachea low down and endeavor to

remove the foreign body or to facilitate its spontaneous expulsion. This opinion was the result of considerable experience.

DR. LEWIS A. STIMSON read a paper on OLD UNREDUCED DISLOCATIONS OF THE ELBOW.

The following papers were read by title:

"Fractures Involving the Upper Third of the Femur Exclusive of the Neck," by DR. O. H. ALLIS, Philadelphia.

"Fractures of the Bones Which Form the Elbow Joint, and their Treatment," by DR. LEVI C. LANE, San Francisco.

"Hemiplegia with Aphasia, Following Ligation of the Common Carotid Artery," by DR. J. EWING MEARS, Philadelphia.

"Investigation of Pistol-shot Wounds of the Skull and their Treatment," by DR. E. H. BRADFORD, Boston.

"The Results of Experiments in the Filling of Cavities of Bones Following Operations for Caries," by DR. E. H. BRADFORD, Boston.

After extending a vote of thanks to the retiring President, the Association adjourned to meet in Boston, Mass., in June 1892.

BOOK REVIEWS.

HEALTH REPORTS.—1. *Eleventh Annual Report of the State Board of Health of New York*. Vols. I and II. Paper. Pp. 935. Octavo. Albany: Jas. B. Lyon.
2. *Thirteenth Report of the State Board of Health of Wisconsin*. Paper. Pp. 150. Octavo. Madison: Democrat Printing Company.

Twenty years have elapsed since the creation of the first State Board of Health in the United States, in Massachusetts, and from that single beginning, State after State has fallen into line, until nearly every State in the Union has its board of health in more or less active operation, according to the appropriations granted them by the various legislatures.

The reports show careful and conscientious work, in furnishing information to municipalities within their boundaries, and the New York report is especially valuable on account of the complete directions given for the sewerage of certain villages and the disposal of the sewage, and rules and regulations for the water supplies of certain others. The treatment of these topics may well serve as a model for similar work elsewhere.

The Wisconsin Board was hampered in the publication of its report by the parsimony of its legislature. The board reprints in its report, with favorable comment, the resolution of the conference of State boards on the subject of the great destruction of forests now going on, and the means of prevention of the deforestation. This subject is one of growing importance, not only from the standpoint of the sanitarian, but as well from that of the publicist. The general encouragement of tree-planting and the laying out of public parks is needed in every State in the Union.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,

No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dnnnglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dnnnglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, OCTOBER 10, 1891.

TOXICITY OF THE URINE—ITS DETERMINATION
AND CLINICAL IMPORTANCE.

Speaking generally, acute febrile processes in the present state of our knowledge, may be divided into two classes, those in which the febrile reaction, with its accompanying nervous manifestations, particularly brain symptoms, is due to the presence in the body fluids of soluble poisons, intoxication; and, secondly, those cases in which the febrile reaction or nervous manifestations are due to, or at least are accompanied by, distinct structural changes. How far the second class of cases may be hereafter shown to belong to the first class it is not our present purpose to discuss. Perhaps it would be better to present the same classification in different terms, and say that there are acute cases in which the symptoms may be made to disappear, promptly and completely, by active eliminative measures, and, secondly, cases in which elimination fails to relieve.

In practice it is difficult and often impossible to differentiate the two classes, and resort to therapeutic measures must be had to determine the diagnosis, measures which, it is needless to say, are highly unscientific so far as diagnosis is concerned, and while often satisfactory, by no means always so.

In the first or toxic class the poisons producing the symptoms will be wholly or in part elimi-

nated by the urine, and examination of this fluid ought to determine the diagnosis at once. And so it would if it were possible to make the examination. But many of the poisons producing the most intense symptoms act in quantities so small as to defy chemical detection in the urine. Again, these poisons are exceedingly numerous, and many of them as yet unknown, and to examine the urine for even the known ones would be a work scarcely possible, even to the trained chemist, with properly equipped laboratory and abundance of time. Moreover, the qualitative recognition of the poisons is not enough, some idea must be had as to their quantities. What is needed, then, is some general reagent by means of which may be quickly determined, first, that the urine is toxic; second, the degree of toxicity; third, the kind of toxicity.

With the present equipment this reagent is not to be found in the chemical laboratory, but is to be sought in the biological laboratory. The reagent which answers the requirements is the animal organism.

SEMMOLA, following the suggestion originally made by BOUCHARD, has recently made some interesting observations in this direction, and in the *British Medical Journal* of Sept. 19, 1891, reports two cases which illustrate singularly well the clinical importance of such studies. The first case was that of a phlegmon in the right arm of a man aged 70, with serious general and especially cerebral symptoms. Some of this patient's urine was injected into a rabbit with the effect of reproducing the toxic symptoms in a more serious form than in the human patient. This demonstrated the toxic character of the attack and enabled him by way of prognosis to foretell that improvement would take place when the uro-toxic coefficient of the urine was diminished, in spite of the fact that, owing to an intercurrent attack of diarrhoea, the patient's general condition seemed to be worse, and when the clinical prognosis was therefore doubtful. By way of treatment he ordered copious draughts of sulphuric lemonade with the object of destroying the circulating ptomaines, and favoring their elimination.

"In the second case—one of fibrinous pneumonia following influenza—whilst the specific inflammatory process successively invaded new zones of pulmonary tissue, there supervened,

suddenly, eclampsia and tetanoid symptoms, which made the medical attendant suspect the onset of infective cerebro-spinal meningitis. The condition of the patient was most serious; a temperature of 40.07° C. (104° F.) pulse 125, respiration 55; fluid yellowish green expectoration, profuse sweating, etc., in short the classic picture of a most violent acute infection. . . .

I did not however feel justified in accepting without much reserve the diagnosis of cerebro-spinal meningitis, and before giving my opinion I caused experiments to be made in the laboratory of my Clinical institute, on the biological analysis of the urine which the patient had passed in the last twelve hours. . . . The injection of 5 c. c. of the urine into a guinea-pig weighing 250 grams, and 10 c. c. into a rabbit weighing 1,050 grams, was immediately followed by general tremors, alternating with tonic convulsions and extreme dyspnoea, exactly resembling the clinical symptoms and convulsions seen in the patient, and clearly showing that part of the dyspnoea, the severity of which was certainly disproportionate to the extent of the pneumonic process, was of bulbo-paralytic origin. I no longer hesitated as to the diagnosis, but declared that the convulsions did not indicate an attack of cerebro-spinal meningitis, but simply a most acute intoxication, due to the formation of new special ptomaines in that great and mysterious biochemical laboratory of which the human organism, when attacked by influenza, is the seat." A more favorable prognosis was made and the patient put on large doses of sodium iodide as a means of elimination. Within twenty-four hours the convulsive attacks ceased, and the urine passed after their subsidence, although the pneumonic process continued with hardly any appreciable improvement, and the temperature persisted at 104° F., showed itself on biological analysis to be inoffensive. In fact the injection of 90 c. c. into a rabbit did not induce the slightest toxic manifestation referable to the classic clinical type shown by the patient.

MISCELLANY.

AMERICAN PUBLIC HEALTH ASSOCIATION.—The nineteenth annual meeting will be held at Kansas City, October 20 to 24, 1891. The Local Committee of Ar-

rangements announces that all the Railway Passenger Associations of the country have granted a one and one-third fare rate for the round trip, on the usual certificate plan, that is: 1. Procure a certificate of attendance from the agent at the starting point by paying full fare to Kansas City. 2. Have the certificate of attendance signed by the proper officer of the Association at Kansas City. This certificate will then procure return ticket for one-third fare. All the leading hotels of Kansas City will give special rates to delegates. Arrangements are being perfected for an excursion into Kansas, as one of the features of the entertainment of the Association. For any information as to the meeting, address Dr. E. R. Lewis, Chairman, or Dr. Joseph Sharp, Secretary, Local Committee of Arrangements, Kansas City, Mo.

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION meets next Wednesday morning at the Pickwick Theatre, in St. Louis. The indications are that the meeting will be very much the largest ever held by this banner organization.

DISTRICT MEDICAL SOCIETY OF CENTRAL ILLINOIS.—The Semi-Annual Meeting of this Society will be held in Vandalia, Ill., on Tuesday, October 27, 1891.

Officers.—President, G. W. Fringer, M.D., Pana; First Vice-President, W. G. Wilson, M.D., Shelbyville; Second Vice-President, Wm. H. Sparling, Moawequa; Secretary, J. H. Miller, M.D., Chicago; Treasurer, F. B. Haller, M.D., Vandalia.

Board of Censors.—W. J. Eddy, M.D., Shelbyville; J. Huber, M.D., Pana; W. W. Murfin, M.D., Patoka; Jno. A. Prince, M.D., Springfield; Amos Sawyer, M.D., Hillsboro.

PROGRAMME.

Tuberculosis, W. J. Eddy, M.D., Shelbyville.

Movable Kidney and Hydronephrosis, David W. Graham, M.D., Chicago.

Acute Periostitis of the Femur, Wm. Barnes, M.D., Decatur.

Report of a Case in Gynæcology, Naomi Pierce Collins, M.D., Decatur.

Dermoid Cysts of the Ovary, with Report of Cases, Louis A. Malone, M.D., Jacksonville.

A proposition to amend certain parts of the Constitution and By-Laws will be submitted at this meeting. You are earnestly requested to be present.

J. H. Miller, M.D., Secy, 113 Adams St., Chicago. G. W. Fringer, M.D., Pres., Pana, Ill.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from September 26, 1891, to October 2, 1891.

Capt. Walter Reed, Asst. Surgeon U. S. A., relieved from duty as attending surgeon and examiner of recruits at Baltimore, Md., and ordered to Ft. Snelling, Minn., upon completion of his duties as member Army Medical Board.

Asst. Surgeon Charles B. Ewing, U. S. A., will continue on duty as attending surgeon and examiner of recruits at St. Louis, Mo.

Asst. Surgeon William D. Crosby, U. S. A., relieved from duty at Ft. Pembina, N. D., and ordered to Ft. Missoula, Mont., for duty. Surgeon James P. Kimball, U. S. A., relieved from duty at Ft. Supply, I. Ter., and ordered to Ft. Clark, Tex.

Surgeon Julius Patzki, U. S. A., relieved from duty at Ft. Huachuca, A. T., on expiration of present sick leave, and ordered to Ft. Supply, I. Ter.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending October 1, 1891.

Medical Director Thos. J. Turner, placed on the Retired List September 21, 1891.

Surgeon Jno. H. Hall, placed on the Retired List September 25, 1891.

Surgeon Juo. C. Boyd, ordered to duty on Naval Medical Examining Board.

The Journal of the American Medical Association

VOL. XVII. CHICAGO, OCTOBER 17, 1891. No. 16.

ORIGINAL ARTICLES.

AMERICAN MEDICAL ASSOCIATION.

SECTION OF ORAL AND DENTAL SURGERY.

The Section was called to order on Tuesday, May 5th, 1891, by Dr. E. S. Talbot, of Chicago, Ill., the Chairman of the Section of Dental and Oral Surgery of the American Medical Association.

Dr. Talbot: The first thing necessary to be done will be to elect a Secretary. Dr. Morgan is unable to be with us at this Section, and so we will have to appoint a Secretary. I propose Dr. Custer.

Dr. Custer: I would rather you would have some one else.

Dr. Talbot: There are no minutes to be read and the duties will not be arduous. Those in favor of Dr. Custer being appointed as Secretary will signify aye.

This motion was seconded and passed unanimously.

Dr. Talbot: It may seem to some of those who are present that the numbers are rather small; but having attended all the meetings since the Section was organized ten years ago, with the exception of one, I can say that it never was intended that there should be a large number attending these meetings. It was intended that those that were invited to read papers should be men of unusual scientific qualities; and that the papers should have their effect upon the medical profession by being published. For this reason the Society has never catered to a large gathering; but there are quite a number of dentists in the city, and to-morrow we may expect to have a larger gathering. There are no minutes to be read; the Section simply keeps a record of the papers that are read at the meeting in a book, and the minutes are not intended to be reported at all. We will therefore dispense with that matter, and the first order this afternoon will be the Chairman's address. I will call Dr. J. L. Williams, of Boston, to the Chair *pro tem*.

Dr. Talbot then read

THE PRESIDENT'S ADDRESS.

Gentlemen:—Dentistry from the earliest period up to the present time has been practiced by medically educated men.

Hippocrates, 460 B. C., speaks of dentrifices and the fixing of the teeth; Celsus, at the end of the first century; Ætius, in the sixth; Egenolff and Ambrose Paré, in the fourteenth. All mention certain forms of treatment of the teeth. John Hunter, 1728, spent much of his time in the study and treatment of the teeth, as well as the study of general anatomy; Fouchard, 1747; Bourdet, 1786; Fox, 1814; Catalan, 1826, all practiced dentistry and also wrote extensively on dental subjects.

The instruments for dental as well as surgical purposes which are to be seen in the museums of Europe, together with the beautiful specimens of Etruscan and Phœnician dentistry now in the possession of Drs. Van Marter of Rome, Barrett of Buffalo, and Taft of Cincinnati, and which are similar to those made to day, are striking illustrations of the superior ability which men of early times acquired.

About 1826-1830, the practice of dentistry was not wholly in the hands of an enviable class of individuals. Many were watchmakers, barbers and tinkers of various descriptions, who had taken up the practice for the money that was in it, and were roaming about the country extracting teeth and inserting artificial ones, regardless of honor and ability.

There were, however, a few medical men practicing dentistry, who had obtained a high standing in their chosen profession, and who were anxious to hold their special calling upon an equal footing with other branches of the healing art. Among those, whose names stand out conspicuously in the history of the country, are. Parmley, Brown, Hayden, Tucker, Hudson, Greenwood, Maynard, Trenon, Harwood, and Chapin A. Harris and Keep.

We can easily imagine the feeling of these men, who by reason of superior skill and ability had attained high positions in their chosen specialties, when they met in council together to discuss the different subjects relating to the standing of the calling with other specialties, and the qualifications for admission to their Society. It

was not until 1839 that any movement was made on the part of these men to elevate their specialty from the slum in which a majority of the so-called practitioners were holding it. It was at this period that one of the most important events in the history of dentistry occurred.

The *American Journal of Dental Science* made its first appearance, with Dr. Chapin A. Harris and Eleazer Parmley as its editors. The American Society of Dental Surgery was organized in 1840, also through his efforts in coöperation. In connection with these movements, it was the ambition of Dr. Harris to organize a dental school in connection with the Medical Department of the University of Maryland. The practice of dentistry (at this time), with few exceptions, being at a very low ebb, did not impress the faculty of the University as being of sufficient importance to be considered a part of the healing art. The request of Dr. Harris was therefore rejected. Whether this request, at this period in the history of dentistry, would have been rejected by the faculty of any other medical college in this country, or whether it would have been rejected if presented to the Medical Department by any other person, or at any other time, we have no means of knowing. Nor do we know much of the general feeling among physicians at that time, in regard to the relation of dentistry to medicine. We only know that the rejection of the proposition gave Dr. Harris new energy, and as a result the Baltimore College of Dental Surgery was established, and that the School of Medicine and the School of Dentistry ignored each other for a time.

Whether the establishment of a strictly dental school, together with the conferring of a separate degree from that of the medical school, has benefited dentistry, it is difficult to say.

The original idea of Dr. Harris, if it could have been successfully carried out, would no doubt have placed dentistry as a calling upon a higher plane than it occupies at the present time. His idea was that by this union the Dental Department, being a legitimate specialty of medicine, would thus draw support from the medical profession at large. Be that as it may, dentistry, forced upon its career with a new degree, had, with very little aid from the medical profession, to work its own way as best it could. This incident marked one of the greatest epochs in the history of our calling.

Like the young man, sent away from the parental roof, dentistry has grown strong in some of its features. The Baltimore College, owing to the talent of unexceptionally able men, flourished, and men of ability were graduated, who practiced dentistry in different parts of the country, with the new degree of "Doctor of Dental Surgery." So successful was this college, that other schools of dentistry were organized shortly

afterward, and these in their turn became as successful as the mother school.

From the first, graduates of dentistry who were ambitious to excel have never been satisfied with a dental degree only, and many men, anxious to acquire higher attainments, have taken the medical degree also. Many of the graduates are anxious to acquire a broader and more liberal education, but time and purse do not permit it.

Dental students have been ambitious to obtain the highest acquirements, and, in many cases, have not been satisfied with the course of instruction in our dental colleges. The dental faculties have been obliged to so shape their course and so far as possible have made arrangements with medical colleges, that by taking one additional course, their students could receive the medical as well as the dental degree. And there has been a desire on the part of both medical and dental graduates to draw the medical and dental schools together, as evidenced by the fact that medical men are anxious to secure positions in the dental colleges. This desire may not have been outwardly intentional on the part of some, but the relations of one to the other are so close that scarcely any distinction really exists. I have frequently heard medical men, those who have had experience as teachers in both colleges, say that they prefer to lecture to dental students.

The first dental college to unite with a medical college was the St. Louis College. The St. Louis Dental College was founded in September, 1866, and the first announcement stated that the students will have the benefit of the lectures in anatomy, chemistry, physiology and materia medica that are given to the matriculants of the St. Louis Medical College, the first college to take the step in this direction.

Following this, in 1867, the Harvard Dental School was organized in connection with Harvard University; since that date most of the universities in this country have established dental departments. The older dental colleges are uniting themselves as rapidly as possible to universities, so that at the present time nearly one-half of the dental colleges are departments in the different universities. Ever since the formation of the Massachusetts Medical Society, in 1781, it has had members practicing dentistry; and the Suffolk District Medical Society, which is a part of the Massachusetts State Medical Society, created a section in 1866 called No. 5, for "Surgery and Dentistry;" this is now a quarter of a century old. In Massachusetts, forty or fifty years ago, no reputable dentist would take a pupil, unless he would engage to take a full medical course, or had already graduated in medicine. Scarcely a dentist who has been in practice for twenty-five years, and who has sons growing up, is not anxious to have them to take a full course in medicine before taking up the subject of den-

tistry, which they regard as a specialty in medicine.

This brief history has been given to show that our best educated early practitioners in dental surgery have always regarded it as a specialty in medicine rather than an independent profession. Dr. Harris so regarded it, and he was the founder of our first dental college, and established this college for the reason that he was not permitted to organize a dental department in a medical college, as he preferred to do. This is evidenced from his inaugural address at that time.

"Allow me," he said, "to observe, however much of interest or curiosity the establishment of this institution may have awakened, it constitutes an era in the history of a most useful and valuable department of medicine."

In speaking of the empiricism that had up to that time existed in the practice of dentistry, he says: "I feel bound to the public and to my own reputation, to denounce the empiricisms that have, and do still exist in the department of medicine." Again he says: "It is to be hoped that the day is not far remote when it will be required of those to whom this department of surgery is intrusted, that they shall be educated men."

Although dentistry apparently seceded from the mother profession in 1840, it was so near akin to it that, with few exceptions, there has been a yearning on the part of the dental graduates to return to the parental roof. Many graduates of dentistry have availed themselves of the opportunity, and the numbers are increasing every year.

With the convening of this meeting, the Section of Dental and Oral Surgery in the American Medical Association enters upon the tenth year of its existence. At the session of the American Medical Association held in Richmond, Va., 1881, Drs. W. W. Allport, J. W. Brophy, E. S. Talbot, Chicago; Dr. J. L. Williams, Boston; Dr. G. L. Goodwillie, New York; Dr. Hauxhurst, Grand Rapids, Mich.; and Dr. G. L. Parmlee, Hartford, Conn., practitioners of dentistry, holding medical degrees, presented themselves as delegates from local medical societies, for the purpose of organizing a Section on Dental and Oral Surgery. Each gentleman constituted himself a committee of one to champion the movement among the members of the Association who were in attendance. They found no opposition whatever; on the contrary, the oldest members, and especially the ex-Presidents of the Association, were heartily in sympathy with the movement, and were anxious to assist in bringing it about. At the morning session Thursday, May 5, Dr. Samuel D. Gross, of Philadelphia, asked for a suspension of the regular order of business, which motion was granted. He then moved that the By-laws of the Association be so

amended as to create another Section, to be known as No. 7, entitled Dentistry. The motion was favored by Dr. Sayre, of New York, and Dr. N. S. Davis, of Chicago, and was adopted. The object of suspending the rules at this time, was for the purpose of creating the Section, so that we might organize and commence work at that session; the members who were to constitute the Section being prepared with papers for that purpose. Dr. Toner, of Washington, objected, saying that he was not opposed to the Section organizing and commencing work this year, but he did not wish to make a precedent for future Sections. It was therefore decided that it could not go into operation until the next year, when, according to the Constitution and By-laws of the Association, dentistry was officially recognized by the American Medical Association.

The effect that this movement produced upon the so-called dental profession was, in one respect, magical. Before this period, scarcely a meeting of dentists convened, without having upon its programme a paper upon the subject of "Is Dentistry a Specialty in Medicine?" Strange as it may seem, many took the ground that it was not, ignoring the fact that it had been practiced as such until, and by some within, the last forty years; that many of its branches were taught by medically educated men, and also that we were practicing upon a part of the human body. Since this period, scarcely a paper has been written upon this subject. The action taken by the American Medical Association, as well as cases which have been lately decided by the courts, have legally settled the question forever.

Fortunately, there is little opportunity for wire-pulling or scheming for political preferment in our Section, for it is well known that the majority of our members prefer that the offices be given to others than to themselves. Thus the time devoted to the Section has been entirely given up to the reading and discussion of papers, and in no dental society in this country, has there been presented such an array of scientific papers as has been given in this Section. The men who have taken part in the meetings of this Section have in most cases been of exceptional ability, and whose standing in the specialty has added dignity to its meetings. The influence of the work in this Section upon the medical profession has brought about a marked change in the Association.

The Section of Dental and Oral Surgery is recognized as a part of the whole, like other Sections, and its members exert as much power in promoting the welfare of the body, as do the members of other Sections. Indeed, the members of this Section have had the pleasure of listening to papers and discussions at its sessions, by some of the ablest men of the Association, which not only added interest to its meetings, but also showed that the members of the Associ-

ation are in full accord with the specialty as a part of the general body.

Since the organization of the Section, editors of medical journals have become quite liberal, as well as more intelligent, in their discussion of dental subjects, and have taken more interest generally in the affairs of dentists; and physicians have accepted invitations to read papers before local dental societies, and dentists have read papers before medical societies. This shows the interest which an interchange of thought is developing, by the union of the different branches of the healing art. Since the formation of this Section, through the efforts of W. W. Allport, teaching in regard to dental diseases has been established in many of the medical colleges of Chicago, which example has been followed in other colleges in the country. One of the arguments used by some dentists against the theory that dentistry is a specialty in medicine, was that the medically educated person knew nothing of dentistry, or those diseases of the oral cavity which result from diseased teeth. Medical men could hardly be expected to know much in regard to the lesions of the mouth, they having received no special instruction upon this subject. The action taken by Dr. Harris and the medical faculty in 1840, no doubt impressed the faculties of other medical colleges with the idea, that lesions of the mouth resulting from diseased teeth were of little consequence, and therefore knowledge of them of little value, to the general practitioner.

Now however, medical men, as well as dentists, know that many lesions of the body are the direct outcome of diseased teeth. In my capacity as a dental teacher in a medical college, I have instructed the students for the past eight years that (in my opinion) many of the diseases of the body, such as pneumonia, consumption, typhus and typhoid fever, eruptive fever, suppuration of the throat and tonsils, aphthæ, ulcers, etc., were the outcome of a collection of microorganisms in the mouth, and decay of the teeth. My reasons for this theory were that, in many instances in my practice, I have observed patients entirely recover from supposed consumption and other bodily ailments, after the mouth has been put in a healthy condition. In one case a lady gained 35 lbs. in weight, a young man gained 13 lbs., and a young girl who had been treated for six months for consumption, and was supposed to be on her death-bed, entirely recovered after having a number of roots of teeth removed and tonics administered. This theory has been confirmed by Professor Miller, of Berlin, who has observed the bacillus tuberculosis and the bacilli of other diseases in the mouth. In his work upon "Microorganisms of the Human Mouth," he shows how many diseases of the body are produced by pathogenic bacteria by inspiration,

absorption, and being taken into the alimentary canal, which have accumulated in the mouth. Today many of the medical colleges of the country have a chair upon dental and oral surgery, and the students are now taught dental anatomy, physiology and pathology. Of the six medical colleges in Chicago, there is not one that does not provide for instruction in these branches by some dentist. No medical student should be allowed to graduate without some knowledge of the laws of diseases, and their effects on the mouth and teeth, and no medical college to-day can be considered complete without a chair upon this subject. In view of the fact that able practitioners of dentistry were debarred from becoming members of the American Medical Association, on the ground that they did not belong to some local medical society, at a meeting held in Chicago, in June, 1887, Dr. Allport conceived the idea of having a resolution passed, which should admit as members men of ability who held the D.D.S. degree.

With the assistance of Dr. N. S. Davis, the following resolution was presented and unanimously adopted by the American Medical Association, 1887:

Resolved, That the regular graduates of such dental and oral schools and colleges as require of their students a standard of preliminary or general education, and a term of professional study, equal to the best class of the medical colleges of this country, and embrace in their curriculum all the fundamental branches of medicine, differing by substituting practical and clinical instruction in dental and oral medicine and surgery, be recognized as members of the regular profession of medicine, and eligible to membership in this Association, on the same conditions and subject to the same regulations as other members.

In the following year, 1888, the Chicago Dental Club, having adopted the Code of Ethics of the American Medical Association, sent the following members to the Association, as qualified under the resolution: W. W. Allport, A. E. Baldwin, John Marshall and E. S. Talbot; and since that year, 1888, the Dental Club has continued to send members to the Association. The adoption of this resolution by the representative Society of the country, would seem to show that the medical profession had done its full part to recognize *properly educated* dentists as legitimate specialists in the practice of medicine. The question of relationship has now been definitely settled forever, and the only question now remaining is this: What proportion of dentists, in the future, will so qualify themselves to practice dental and oral surgery, that they will have the right to be classed as medical specialists, the same as surgeons and ophthalmologists, and entitled to recognition in the Association, in accordance with the letter and spirit of the resolution referred to?

Professor Garretson, in a letter to me, states that in the Philadelphia Dental College, which is in connection with the Medico Chirurgical College, the following distinction is made between

the course conferring the D.D.S. degree and the one conferring the M.D. degree, or both: On matriculation, the student signifies his intention to take the M.D., or a dental degree, or both. If he chooses the course conferring the dental degree, he is taught only such branches as pertain to the treatment and filling of teeth. On the other hand, if he signifies his intention to take the M.D. degree, or both, he receives instruction in the branches that will fit him to practice oral surgery, or oristry, and medicine, as well as dental surgery. The professional position that the educated dentist occupies at the present time, could not be improved upon, as is true of the position he holds in society. His relations with the mother profession are as free and broad as the air of this great American Continent. It now remains for him to decide whether he will be satisfied with little education—with an education that permits him to see only faintly, and to realize not at all, the possibilities of his profession, and renders him content to grope along in the lower stratum of his practice, seeing and wishing nothing higher, possessing only narrow views in regard to his calling, attending no societies, or only those whose time is given to discussions on such subjects as red rubber, amalgam and root filling, extraction of teeth and insertion of artificial dentures. If he is content with these things, and looks upon the profession of dentistry as a trade, merely as a means of subsistence, with as little expenditure of power and thought from himself as possible; will he rest satisfied with this position, or will he take a broader view of the situation, looking at dentistry from all sides, thinking the subject worthy of all his power, all his talents and ability, striving to make it equal to the mother profession, and educating himself so that he may stand upon an equal footing, shoulder to shoulder with the best medical men in the country?

Some one may say that he has not the time nor the money for this. In answer to this, permit me to refer to a Professor in the University of Berlin, to show that it is possible for a poor American boy to *educate* himself for the practice of dentistry.

His worth was recognized by the faculty of the University of Berlin, and a position was offered him as Professor in the University, an honor that has been accorded to no other American. And during my late visit to Berlin, it gave me great pleasure to observe the respect shown by the faculty of the University, Government officials, as well as the highest officer in the International Medical Congress, to Professor W. D. Miller. This example is only given to show that to him who works in the right direction, all things are possible, and the higher he places the limits of his attainments, the greater will his attainment be.

Let the dentist be a scientist, and not a medi-

ocre and narrow-minded tradesman. Let him select a new mark every day, at which to aim his energies and talents, and let that mark be ever ahead, and ever on a higher plane.

Dr. Williams: Unless the writer invites discussion, we will simply pass the paper as it is.

Dr. Talbot: The next paper upon this programme is by Dr. Wm. Carr. In order to facilitate the reading of papers it has been decided to set apart to-morrow afternoon, from three to half past five, for the purpose of hearing papers by Dr. George S. Allen of New York, and Dr. R. R. Andrews of Cambridge; and we have a paper by Dr. A. H. Thompson, of Topeka, Kansas. Dr. Thompson was unable to be present.

Dr. Marshall: Mr. Chairman, I would move that a committee of three be appointed to whom the papers shall be referred before being read.

Dr. Williams: It is customary, I think, to appoint a committee of three.

Dr. Talbot: The motion has been made that a committee of three be appointed, which is always customary in the Sections, to whom the papers shall be referred before reading. I will appoint Drs. Williams, Marshall and Andrews.

Dr. Marshall: It happens, Mr. Chairman, that each one of that committee has a paper of his own to read.

Dr. Talbot: I will refer those papers, then, to members of other committees. I would suggest to those who have papers that they submit them to the committee for approval. That is a matter of form. What shall we do with Dr. Thompson's paper; shall it be read this afternoon?

Dr. Marshall: I have been looking it over. It is interesting from the standpoint of a comparative dental anatomist. It is on that subject. It will take too long now to submit this paper to the approval of the committee, and I have not quite finished reading it.

Dr. Noble: I would like to remark that Dr. Edward Maynard died last evening, and I feel it would be highly proper for you to take, at this very first meeting, some steps in reference to his death, and that proper resolutions should be drafted and that a delegation be appointed.

Dr. Andrews: I did not know he was so near death. I think the suggestion a good one.

Dr. Noble: I presume the announcement of his death will probably be in the evening papers. At the last meeting of the Section in Washington I know there were quite a number who took a great deal of pleasure in visiting Dr. Maynard, and I think he came to one of the meetings. He certainly was a man deserving of respect and appreciation. I should hope that some action shall be taken.

Dr. Williams: I move that a committee of three be appointed to draft suitable resolutions on the death of Dr. Maynard.

Motion seconded and passed unanimously.

Dr. Allen: I would like to include W. H. Atkinson with Dr. Maynard.

Motion seconded and passed.

Dr. Noble: I wish to say that our old friend Dr. Maynard came to this city about thirty-five years ago. I came here as a young man and as a student, and I well remember at that time with what veneration we looked up to Dr. Maynard, who was then in the very height and pride of his national reputation. I wish to bear personal testimony to his wonderful skill with his fingers; his manipulative ability, not only in the matter of filling teeth, but his knack in the way of using tools and instruments in the laboratory. One of the most wonderful men I ever knew with reference to executing what his brain thought out; and we all know what a large brained man he was; and that for many years he was looked upon as one of the leaders in our profession in all things that pertain to advancement in the way of mechanical appliances. He was one of the first to thoroughly remove the nerve, and probably with more thoroughness than was done before or for some years afterwards. This was mainly due to the care which he took in preparing the fine nerve broaches which we are now familiar with. I also feel proud of having his name on my diploma along with that of Drs. Harris and Bond. I think there is only one man living that was on my diploma, and that is Professor Sterner. I feel deep sorrow to hear of the death of Dr. Maynard. Of latter years you have not heard very much of him, and I am sorry to see there has been some language used with reference to Dr. Maynard that seems to me uncalled for; that he has not taken an active part in societies, his age preventing. I hope we will always be ready to say, peace to the ashes of Dr. Maynard; for he certainly was deserving of veneration. As an operator he stood at the very top of our profession. He was always dignified, and as we all know bound up with our profession.

Dr. Talbot: Those in favor of the resolution offered by Dr. Williams, please manifest by saying aye. Seconded and passed unanimously.

Dr. Talbot: I will appoint on that committee Dr. Noble, Dr. Allen and Dr. Williams.

Dr. Marshall: Mr. Chairman, I have been over the paper of Dr. Thompson's and think I can get through it.

Dr. Talbot: The next paper then in order will be that written by Dr. A. H. Thompson of Topeka, Kas., on "The Teeth of Invertebrate Animals." It will be read by Dr. Marshall.

Dr. Marshall: This claims to be a type-written copy of the paper, but whoever did it did not know very much about typewriting. It is not well printed and it is on extremely thin paper, and I can only see it by holding it in a rather awkward way; so that if I stumble it will be because of poor printing.

(Dr. Marshall then read the paper.)

THE TEETH OF INVERTEBRATE ANIMALS.

BY ALTON H. THOMPSON, D.D.S.,
OF TOPEKA, KAN.

The resources of Nature are infinite. The expedients to which she resorts are marvelous and endless in their variety. When new conditions are to be met, her invention is never at a loss, and her capacity for change is boundless. Environments change and corresponding alterations in organs arise to meet the new conditions presented. The life of a species depends upon this power to change, to conform to new environments. The law is adaptation or extinction.

In no set of organs—in animal life at least—is this infinite variety of resources, or the capacity for change, or the power of invention, so fully illustrated, as in the teeth. Food selection has created a wonderful variety of forms of teeth which have arisen in response to changes in the food environment. Those species which could conform to gradual change, survived and transmitted the acquired modifications in the dental apparatus. Those which could not change, perished; or escaped to a more favorable food environment. From such causes many variations in the teeth of animals arose in the course of the geological ages, and, taking the living and the extinct species altogether, the number and extent of these variations is beyond estimation. The variety presented in the different forms of teeth and masticating apparatus throughout the animal kingdom, illustrates and exemplifies the fact that these organs are susceptible of great variation, and that the possibilities of change and the invention of Nature, are especially marked in these organs.

If vertebrate animals present great variations, and many extraordinary forms and interesting extremes in the structure of the dental armature, so also do the invertebrate animals, although these are not so well known. To the naturalist and the philosopher the latter are equally interesting, however, and serve to enlarge our views of the wonders and beauties of nature. To the dental student the teeth of invertebrates are interesting from the comparative standpoint, and serve to illustrate the remarkable possibilities of dental variation, and help to better understanding of the principles of the mechanical evolution of the teeth of animals. In such studies, any knowledge is valuable which may contribute, even remotely, to a better understanding of the important organs which we are called upon to preserve, and thus better prepare us for our chosen work. The study of comparative anatomy is of great value for the side lights it throws upon the teeth of man—their origin, evolution, mechanical design, etc.,—and therefore we claim that the

study of a branch, even as far removed from man as the invertebrates, is of sufficient value to warrant us in presenting a brief epitome of our knowledge of this branch; by way of stirring up an interest in it as an incentive to further study and investigation.

Professor Huxley says, "Anatomy of Vertebrates:" "When invertebrated animals are provided with teeth or masticating organs, the latter are either hard productions of the alimentary mucous membrane, or are modified limbs, as opposed to vertebrated animals, which also usually possess hard productions of the alimentary mucous membrane in the form of teeth; but their jaws are ordinarily parts of the walls of the parietes of the head, and have nothing to do with the limbs." The vertebrate jaw is part of the endoskeleton—the invertebrate jaw belongs to the exoskeleton, as do the teeth of all classes of animals, as illustrated by their embryology.

Mr. W. H. Dall says, "American System of Dentistry:" "Almost every large group of organisms below the vertebrates, until we reach the Moluscoidæ and lower radiated animals, exhibits in some of its members, one form or another of prehensile or masticatory apparatus connected with the alimentary canal. None of these exhibit true homologies with vertebrate teeth, though some of them present remarkable similarity to the latter in external relation. . . . They are divided into manibular and dental appendages in the sense in which the latter may be said to exist in the invertebrates. . . . Throughout the invertebrates the teeth are dermal structures, however much modified, and may consist of calcified connective tissue, of horny matter, or of chitin or an allied substance. . . . The teeth and jaws of mollusks, the nippers, mandibles and setæ of worms, are composed to a greater or less extent of chitinous material."

Prof. A. S. Packard says, "Standard Natural History:" "Hard bodies serving as teeth occur for the first time in the animal series, in the sea-urchins, where a definite series of calcareous dental processes or teeth, with solid supports and a complicated muscular apparatus, serves for the comminution of food. . . . Among the worms the organs of mastication for the first time appears in the Botatoria, where the food, such as infusoria, etc., is crushed, and is partly comminuted by the well marked horny and chitinous pieces attached to the mastax. In most other low worms the mouth is unarmed. In the leech there are three, usually in the annelids, two denticulated or serrate, chitinous flattened bodies situated in the extensible pharynx of these worms, and suited for seizing and cutting or crushing their prey.

"In the higher molluscs, such as the snails and others, besides one or more broad pharyngeal jaws, comparable with those in the worms—is

the lingual ribbon, admirably adapted for sawing or slicing sea-weeds, or cutting or boring into hard shells, acting somewhat like a lapidary's wheel; this organ, however, is limited in its action, and in the cuttles, the jaws, which are like a parrot's beak, do the work of tearing and biting the animals serving for food.

"In the crustaceans and insects we have an approach to true jaws, but here they work laterally, not vertically, as in the vertebrates; the mandibles of the articulate are modified feet, and the teeth on their edges are simply irregularities or sharp processes, adapting the mandibles for tearing and comminuting food. The numerous teeth lining the crop of crustaceans and insects, serve to further comminute the food, keeping the larger particles back till finely crushed."

Professor Bradley says, "Manual of Compar. Anat.:" "The lowest forms possess no teeth, except some ciliate infusoria, which have an internal cylinder of parallel rods for the mastication of food. . . . In the Rotifera the denticles are in the shape of denticulated plates. The Echinodermata have five large teeth placed in the formidable apparatus called "Aristotle's Lantern." In the Annulosa the leech is the only member that possesses teeth, the semi-lunar plates imbedded in the muscular walls of the mouth; but the remaining classes have only mandibles and maxillæ which are very hard and chitinous. Among the Molusca, the Gasteropods possess a strap-like organ, the odontophore, which is studied with teeth. Cephalopods possess horny jaws which move vertically. Some other classes have denticles besides."

"In the Annelids (Dall, op. cit.) so-called teeth occur in many groups, but partake rather of the nature of jaws than teeth. This group comprises most of the worms, as well as the leeches. Their bodies are divided into more or less well defined, regular segments, and in general the jaws are on the second or buccal segment, or on a proboscis which is itself on the outer edge of this segment, and may be protruded from the mouth to a considerable distance. They are chitinous, most commonly paired, lateral and opposite, of almost infinite variety of forms, resembling in a general way the maxillæ of insects, and mimicing in miniature, hooks, combs, saws, rasps, claws, etc.

"In the leeches the mouth is provided with three lenticular jaws, with the projecting edges finely serrated, having a partly rotary motion about a point central to the three. The medicinal leech has two rows of serrations on each jaw.

"Among the crustaceans—lobsters, shrimps, crabs, etc.,—the maxillary organs are but modifications of entire limbs translated from the locomotive series and set apart as special mouth organs. . . . In the higher crustaceans the

anterior part of the stomach is provided with certain masticatory appendages or stomacholiths, often termed teeth, though more analogous to a sort of a calcareous gizzard. These consist of several calcareous pieces, moved by appropriate muscles inserted in the membrane wall of the stomach, armed with a smooth medium plate and lateral molar-like organs, whose mimetic resemblance to the molar teeth of some forms of mammalia affords a beautiful illustration of the way, through the selective influence of similar functions, analogous structures may be built up in organs which have no homology whatever. Two smaller points, bicuspid in the lobster, tricuspid in the crab, complete the calcareous apparatus.

"Among the schinoderms, the sea-urchin has a remarkable apparatus called "Aristotle's Lantern," which contains what may be fairly regarded as true teeth. . . . It is very complicated in its arrangement, but in essentials consists of five hard, calcareous wedge-shaped sockets or alveoli, each containing one porcelainous chisel-shaped tooth. The teeth are, like those of rodents, usually worn more on the inner than on the outer side, and therefore in wearing always preserve a sharp edge. The combination of the teeth and alveoli produces a pentagonal cone, the apex being formed by the coming together of the points of the teeth. In life this cone is concealed within the tissues, only the points of the teeth projecting."

Not many of the Mollusca are provided with teeth; the entire group of Acephala (the headless molluscs, such as clams, oysters, mussels, etc., are entirely without head or dental apparatus. And not every one of the Cephalopoda (whelks, snails, periwinkles, etc.,) are provided with teeth, but most of them have such organs. When they are found they are arranged on the "odontophore," a chitinous band upon which the teeth are set, pointing upward and backward like the papilla on a cat's tongue, and it grows out of the radular sac in the floor of the gullet. The floor of the sac is carried forward, with the radula upon it over an arched, cartilaginous mass called the buccal cartilage, and down to the front edge, immediately behind the mouth. This serves as an elastic pad which may press the denticulated surface of the radula against any object to be torn or cut. This is controlled by muscles which draw it backward and forward, or even protrude it, as can be seen in the common wood snail, in which the pink buccal mass is pushed forward to seize and cut food. In the snail the number of these teeth is remarkable, 12,000, to 40,000 have been counted on the saw-like lingual ribbon. It can cut grass or leaves sharply off. As the teeth are worn off the ribbon, it is uncoiled, and new teeth are thus brought into use. The upper part of the mouth is lined with a horny substance, against which the sharp-toothed tongue works with a

rasp-like motion. The tough leaves of the lily may often be found cut by the snail's lingual ribbon.

"The teeth on the strap-like odontophore are varied and remarkable in shape and size, and are difficult to examine, as some of them are very minute and hard to dissect out and study. They are usually composed of a base, a shank or stem, and a cutting edge, the latter simple or variously denticulated. The form of the cutting edge is varied, the carnivorous forms usually having simpler and more claw-shaped teeth. When arranged in rows, as they are in many forms,—the middle row is called the median or *rachidian* teeth, and the lateral rows, the lateral or *pleural* teeth. The latter are usually right and left.

Sometimes there are teeth outside of the lateral rows which are called the *Uncini*, and are flat, plate-like, or slender, spiny teeth. They may be very numerous, as in the vegetable feeding snails, or wholly absent in other forms."

There is much to be observed about the teeth of the snails and their allies, and the field offers a profitable opening for investigation. They are already divided into classes by an elaborate system of arrangement, but much remains to be done in describing varieties. "The adult perfect teeth vary from nearly transparent to an amber yellow or reddish brown, and sometimes the cutting points are black. In any large whelk they are easily seen, and in a large cuttle fish the radula may be an inch wide. On the other hand, in some small land snails, where the whole shell is not larger than a pin-head, high powers are necessary to observe them. . . . The highest type in the system of classification is called the *Toxoglossa*, or arrow-toothed, from their narrow, round form, often barbed, and sometimes hollow to inject poison—as in *Belaor Conus*.

Next come *Rachiglossa*, having only rachidian teeth, as in the common whelk. The teeth are usually slight and varied, and prettily denticulated on the cutting edge. The next is the *Tenio-glossa*, bent-toothed, including the greater part of the fresh water snails. The *Ptenoglossa*, feather-toothed, are a small group, of which the sea-laria is a member. The *Rhiphidoglossa*, needle-toothed, comprise a large number of sea-snails, and a few operculated land snails. The last is *Docoglossa*, chevron-toothed, and includes the limpets. Some snails present a pavement-like form and arrangement of teeth, which are often of a very pretty pattern, or again a mere hardened mass.

We have thus given briefly the outlines of a study of the teeth of invertebrates, merely to indicate the extent of the subject, and to suggest the interest and attractiveness there is in its pursuit to the naturalist; and in addition to this, to suggest that the study of invertebrate odontology has a positive value to the comparative dental

anatomist, from a philosophical standpoint. As a leaf from the great book of Nature, it unfolds to us many of her beauties and wonders, and it is also pregnant with suggestions to the dental student who follows his subject out into all of its branches. So we find in this branch, varieties of form and adaptation to purposes which are not paralleled in the vertebrates. The study of their forms and fitness to perform particular duties, is full of interest and surprises, in the fertility of design which Nature exhibits. Then the analogies presented are very interesting, as in the case of the cuspidate teeth of the stomacholiths of the crustacea, which resemble vertebrate grinding teeth, and show that similarity of function often develops similarity of form, even in dissimilar parts. Of homologies with vertebrate teeth, there are few, as the jaws of the articulates work horizontally and those of vertebrates vertically. In the few instances of invertebrates which have vertical jaws, those parts are armed with beaks and the teeth are situated further back on the odontophore. The teeth of the sea-urchin have true sockets and alveoli, but their arrangement, support, and motion are very different from those of the vertebrates. So that taken altogether, the class presents few homologies with vertebrates, or even resemblances to them, and thus affords a variety of illustration that the latter does not supply.

Dr. Talbot: You have all heard Dr. Thompson's paper read by Dr. Marshall. Are there any remarks?

Dr. Whitefield: There is very little I could say on the subject. Last summer I was very much interested in the study, and I have some teeth at home which I think are nearly three-eighths of an inch long and the arrangement is very beautiful. There is a little skeleton-like arrangement something like a trap, coming to a point, and the tooth presses down over that point. They all work separately.

Dr. Rusk: A few days ago, I saw a specimen which I would like to show here, and will bring here some time during the session. It is a very large tooth that was sent here by some chief in the west, and the remarkable part of it is that the enamel is black or almost black. It is a very immense tooth with very short roots. I think it is a very rare specimen.

Dr. Talbot: As the sessions are to be very short and we have to leave the room at half-past five, and as there are a large number of papers, it would seem to be a good plan to have another one this afternoon, so as not to crowd them in the last session; and I would suggest that Dr. Marshall read his paper.

Dr. Andrews: I think it would be better to have Dr. Marshall's paper held over until another meeting. It is an interesting paper and there will be more members present.

Dr. Talbot: What is your pleasure in regard to the matter? I would suggest adjournment.

Dr. Marshall: I move that a nominating committee of three be appointed, to nominate officers and report to-morrow afternoon. Seconded and passed unanimously.

Dr. Talbot: I appoint Dr. Marshall, Dr. Taft and Dr. Williams. The motion to adjourn is now in order. Seconded and passed.

WEDNESDAY, MAY 6.

The meeting having come to order, Dr. Talbot occupied the chair.

Dr. Talbot: The first order of business this afternoon will be the election of officers. According to the Constitution and By-laws, officers are to be elected the "second day of each annual meeting." I believe a committee was appointed to attend to the matter, and as this is the time for that order, we shall have to take it up at this hour. Have the nominating committee any report to make?

Dr. Marshall: Mr. President, the committee has not been able to get together yet, but we will make a report after the discussion closes.

Dr. Talbot: If there are no other committees ready to report, the next order of business will be papers from Dr. Geo. S. Allen and Dr. E. Andrews.

(Dr. Allen here read his paper, after which he illustrated the same by stereopticon views.)

THE GENESIS OF THE CONTOUR FILLING

BY GEO. S. ALLEN, D.D.S.,
OF NEW YORK, N. Y.

So generally accepted is it by the profession at large that the contour filling represents the highest development of the art in conservative dentistry, that it is as much as a man's reputation is worth, to say a good word for the old-fashioned face filling of years gone by. Practice and precept, it is true, do not always follow the same road; still it is a healthy sign of growth to see the highest ideal kept well in the foreground in all our discussions and writings. No subject has been so well and so ably handled by the wise men in our profession, as the one that presses the claims and advantages of contour work. So true is this that he who would start on the hunt for one single brand new thought or idea on the subject, would have a weary road to travel and have little to show for his time and trouble when he came to foot up his returns.

At the best he could only hope to attract attention by giving some more beautiful or apt illustration to some well-worn idea or principle that had already become the common property of all. So I turn aside from this uninviting field of labor to another—one more practical, and I hope therefore more interesting, and will confine my thoughts

entirely within the lines marked out by the title of my paper: The Genesis of the Contour Filling, or how it is made. And this I do for the further reason that so far as I know the cardinal rules to be kept in mind in this kind of work have never been presented to the profession in short compass.

Even within these lines I doubt much whether I can give you much that is new. Still, I think a little less attention has been given to practical instruction in building up the contour filling, than to preaching about its many advantages and beauties. This close attention to one thought will also preclude entering into any discussion as to when and where to attempt the full restoration in the shape of the tooth under treatment. Individual judgment largely controls practice in all cases, and the wise dentist, like the wise physician, always adopts the elective motto. The wisest short law I have ever seen pertaining to this point, came to me in a private letter from an acknowledged authority on the subject, and sums as follows:

"To understand me more completely, I would state that I have not for a considerable time been in favor of inserting very large gold fillings in this manner, and for the reasons you have given in your paper, that the structure and elements of the tooth are not such as to promise a durable retention of the mass of gold, by the weakened tooth. But for medium-sized and small cavities, I am equally convinced from long experience and observation of my own, and the work of others, that no other method offers the same degree of permanency or usefulness."

By so doing he placed himself in the position of the philosopher who said he always obtained what he wished for, and added, sotto voice, "I take good care never to wish for what I cannot obtain."

Taking up then, the building or making of a contour filling, a threefold division of the subject naturally presents itself:

1. The preparing of the cavity. 2. The placing therein of the filling material, and, 3. Finishing and polishing the completed work.

Now a good deal that may be said about the preparing of the cavity will apply to the simpler and easier operations of face and crown fillings; but this one wide difference must be constantly kept in mind, viz: as the size of the cavity increases, the difficulties and dangers increase, not proportionately, but in a geometrical ratio, and therefore a relatively greater care and attention must be given to all the details of the longer and more complex operation. A few quick sharp cuts will suffice for preparing a simple crown cavity, but they would fall far short of filling the bill in any case that we propose to consider this evening.

As the architect or engineer sees his complet-

ed work, before the actual is even started, so should the dentist be able to discern the full size, shape and figure of his proposed restoration, and each step should be so carefully planned and made to fit the next, that in the completed whole, nothing may be wanting.

Very much of success depends on bearing this safe rule in mind. In fact, it is difficult to conceive how one can plan wisely unless he does. On the size and shape of the cavity, on the proper distribution of retaining undercuts or pits, so as to protect and strengthen weak walls and throw the burden on strong ones, much good judgment can be placed, and the writer is convinced that just here may be found the cause of many failures. Undercuts are made too deep, and retaining pits made in such positions or manner as to either weaken the tooth or endanger the pulp.* Deep undercuts, though they make operations easier, are seldom called for, and endanger the completed work, and they do this in two ways: 1st. By weakening the walls of the cavity, and 2d. By making real obstacles to forming a homogeneous, well-packed filling.

The deep undercut, though it holds the great bulk of the gold in place, is itself difficult to fill. To do so well, takes much time and care, and the use of exceedingly small pluggers, and this they may not receive. Where all the walls of a cavity are standing, and the face of the tooth adjacent to the cavity is perfect, the walls of the cavity should be left as nearly parallel as possible, and no pits of any kind made. In fact, nearly parallel walls should be the rule, and pits always avoided, when possible.

The real study and judgment is called for in those cases where the natural face or faces of the tooth have been lost, either by decay, or the too free use of the file and chisel, for, as will be referred to a little later on, in speaking of packing the gold, a point of considerable interest and value arises in these cases, as to whether the filling should be allowed to overlap the walls of the cavity, and simply lie against the face of the tooth on the outside, or shall be made continuous with the walls of the cavity, and bulge only from the cavity itself.

Believing fully as I do that overlapping gold is gold in a dangerous position, I would strongly advocate such a preparation of the cavity as will minimize this danger, even if by so doing, the full realization of our ideal in contouring be not carried out.

It is a sort of belief with many, that in all cases, the packing of gold should be commenced at the cervical wall or base of the cavity. This is a mistake. Oftentimes more certain and rapid work can be done by starting the filling back in the grinding surface, and building downwards. And so this point should be considered, and the cavity shaped accordingly.

As the enamel forms the edges of most large cavities, its proper management is a point of interest. Long ago I advocated in a paper read before the New York Odontological Society, the complete removal of the thin edge of the enamel often found at the neck of the tooth, and this I did for the double reason that it was only slightly adherent to the dentine just there, and so liable to split off during the operation of filling, and secondly, it was very difficult to make a smooth edge on it.

Since that date, I have seen no reason to alter my judgment in respect to this method of practice, but have had many confirmatory ones brought to my notice. Leaving the thin edge leaves a weak spot, and that is bad.

A final point to observe in shaping the cavity, consists in making the edges smooth and polished, and just here the great advantage of the dental engine, with its rapidly revolving bur, comes to the front. No hand instrument, no matter how much care is used, can compete with it. A sharp, well-cut bur will do in a few minutes, far more effective and perfect work, than the sharpest hand instrument can, in a far longer time. If, in addition to the bur, the edges are polished with the wood point armed with powder, or still better, with an uncut round soft iron point, armed with diamond dust, perfect edges can be quickly obtained.

We come now to what many will think the most important part of the work, and the one in connection with which probably more science and skill can be employed than in any other. Two great essentials are to be here considered: The perfect adaptation of the gold to all the walls of the cavity, and the accomplishing this with a minimum amount of force, and a third may be added; that the filling may be made homogeneous and solid throughout.

Imperfect adaptation makes failure almost a certainty, and undue force (and by this I mean any amount of force over and above that required to condense the gold), is almost equally fatal in the end. How then, first of all, shall we proceed to make the gold fit the cavity?

The quality in gold that we make use of in building up a filling of this character, viz: its welding property when pure and freshly annealed, is not one that can be trifled with. It is our servant if we handle it rightly, our master, if we slight it in any particular.

In skillful hands, pure gold is almost as pliable and obedient to the touch, as the clay the sculptor uses to fashion the child of his fancy, but there is this difference: the clay can be worked over and over again, a little added here and as much taken off there, and so long as it is kept moist, it responds to the brain back of it; but not so with gold. Place a bit in position in such a manner as to ensure perfect contact with that already in place, and the union will be perfect,

and it becomes a part of it; but you cannot try a second time; the first is the only one that will be allowed you; if it does not take its proper position at once, you may be sure that something is wrong, and you cannot make that wrong right by using extra force. The moment that is done, the evil that resides in the metal, and that heretofore had been dormant, manifests itself. It becomes stubborn, brittle and cranky, and will not do anything you want it to do, but will persist in doing everything you most object to; like some individuals it has a dual nature, and we must beware how we call out the perverse side.

Then again the amount of force used must always be proportionate to the size of the pledget to be packed, and exactly, too; not enough force fails to insure solidity, and too much has a tendency to bring out the harsh qualities alluded to. As the pledget must be packed in the exact position in which it is first placed, and cannot be moved from it, great care and good judgment are required to avoid pits, and to make certain that the surface is kept even, for it is much more difficult to fill a pit or sharp depression, than to continue a flat surface; and the permitting of pits near the walls of the cavity is especially to be avoided, for the extra force necessary to fill them, too often weakens the walls or even crumbles the enamel. So the rule to be observed is to, as far as possible, carry a uniform surface upwards, and as the filling grows keep the marginal portions a little in advance of the centre.

Another advantage that results from this plan of procedure, is that it makes more rapid work possible, in that you can use larger points. A pit or depression near the walls necessitates the employment of small points, for the point in use must always be a trifle smaller than the pit to be filled. This suggestion is by no means an unimportant one, and a little thought will soon convince one of that fact. The correct packing of gold is in truth an art of itself, and requires an educated touch, and correct eye.

The celebrated painter, Meissonier, always took the greatest care of his hands, keeping them scrupulously clean, and even tender, by the constant use of gloves. He said that a painter's touch must be most sensitive and delicate. So it should be with the dentist, and he ought to be just as careful and particular. Long finger nails, or callous finger tips are to be avoided.

Where to start a filling is a matter of some moment. It is generally commenced at the cervical wall, but cases frequently occur where the commencement may be made with advantage back on the grinding face of the tooth, and the filling carried backward or forward to the floor of the cavity. An advantage frequently arises from this method, for by carrying the gold along the sides of the cavity towards the bottom, any movement of the gold is avoided, and pits to ac-

comply with this same purpose are not required. Anyone who has not tried this plan will be astonished to find how frequently it facilitates the operation. Deep pits in the writer's opinion are great nuisances, and are only admissible when other means fail to accomplish their purpose.

What has been said regarding the manner of making a filling, leads naturally to a consideration of the points to be used, their shape and the best methods of applying the force necessary for condensation of the gold. If the gold is to be built up layer by layer, in a series of plains, the thought naturally suggests itself, that the shape of the points should conform to that of the plains themselves, in fact, should have flat surfaces, and this will be found to be a correct statement. The late Dr. Varney was the first to incorporate this principle in a series of pluggers especially intended for packing cohesive gold, and the set made from patterns furnished by him, to this day stand unequalled for their especial adaptation for contour work. The points all have plain surfaces, and are very finely and evenly serrated. Slight modifications only have been made in them since his day, so completely did he work out his theory in steel.

A round point may have some limited utility at times, but never can be relied upon to any extent. It would be a matter of the greatest difficulty to make a large, uniformly-packed filling by their use only. Deep serrations are faulty in that they cut the gold and require extra power to force the gold into a solid.

How to apply the requisite pressure is now to be considered, and possibly it is the most important consideration of all—how to apply just enough force for the purpose, and to apply it quickly, uniformly and evenly; how to apply the "quantum sufficit" and no more, and in a manner to give your patient the least discomfort, and lighten the labor of the dentist, is a serious problem.

I take it that few would seriously consider hand-pressure alone as offering the best solution. Let alone its being the most laborious and tedious method, it rarely produces perfect work. We cannot get along without it, especially in commencing operations; but good judgment and good work alike demand that it be supplemented by some means more under control, more direct in its action and developing more power; and this can only be done by resorting to some one or more of the various devices which the ingenuity and thought of the profession has placed in our hands the utilizing the power of momentum, or, in plainer terms, the mallet.

The late Dr. Atkinson, whose memory we hold in respect, and whose loss we deplore, was probably the first to suggest this means of obtaining the desired end, and in his hands, and in the hands of his followers, the hand mallet

was made to do most excellent service; but it was soon found that it offered only a partial solution of the problem; to mallet for oneself, was awkward and oftentimes impracticable, and the impossibility of making two brains work in harmony, made the assistant malleter as often a nuisance, as a help; and careful operators soon gave it up, as being impracticable. The automatic mallet, in some of its various forms, took its place, and so well did it do its work, that it will probably always hold its own, and retain a well-deserved place in the dentist outfit. Then followed the electric mallet, a step in advance and a big one; but it had many inherent defects, that greatly impeded its general adoption.

To-day, the mechanical mallet is slowly but surely coming to the front, and the writer feels certain that the day is not far distant, when it, in some of its modifications, will supercede all others, and for reasons that will now be stated as clearly as possible.

Let it be premised that the more closely the force required can be made to simulate hand-pressure, the better it will be in all ways, safer for the tooth and easier for the patient to bear. Now this is just what the mechanical mallet does, in truth, it is pressure intermittently applied, and in no wise is to be likened to the hammer-like blow that is given either by the hand mallet, the automatic, or the electric.

Take a look at the mechanical mallet in operation, and notice how it works. You will see that the point is placed in contact with the gold and gently pushed forward. This throws the further end of the mandril holding the point back, so that the lug or rounded bit of steel with which the rapidly revolving wheel is armed comes in contact with it and it is pushed forward, and this is repeated with every revolution of the wheel, so that from 1,000 to 3,000 impulses may be given to the point every minute, the direction, number and power of these impulses being perfectly under the control of the operator.

In the mallet I employ, which is the Bonwell mallet, as modified by Dr. S. Perry and Mr. Weber, there are 80 threads to the inch in the adjusting screw, and 40 notches in the collar, so that a movement of the collar one notch brings the plugger mandril $\frac{1}{32}$ of an inch, or the thickness of the diameter of a human blood corpuscle, nearer to or farther away from the revolving wheel; and yet, small as the distance is, it is distinctly appreciable to the operator and the patient alike. Does it not look reasonable that a forward push movement of the point, through these small distances, must be comparatively safe and can be made to expend itself in the packing of the gold, and the packing only?

A valuable point I have observed is that where the serrations of the point are rightly made, that is, having one side longer than the other. the

point travels over the surface of the filling and has simply to be guided by the operator, so that if placed near the centre of the filling, it will move over the face of the gold in just the direction and manner required. Thus it becomes the easiest thing in the world to pack towards the walls of the cavity. The gold is plastered in position, as it were, easily and rapidly.

The kind and quality of the push can be regulated in several ways other than by the adjustment collar: by increasing or diminishing the speed of the motor, a great change is at once perceptible; and, again, the educated touch will hold the point against the gold so as to ensure perfect packing, and no force wasted. In fact, through a wide variation of power, it is under perfect control.

A few words in closing, on the finishing. This is a matter of detail, and often of sad neglect. Too high a polish cannot be given to the perfected work. Do the best we can, and we will fall short, far short, of Nature's model. Time and labor cannot be thrown away, if intelligently employed in the finish.

I mentioned in speaking of packing gold, that solidity and homogeneity were essential considerations. I grant that a filling that is hard enough to resist pressure, and is perfectly adapted to the walls of the cavity, will prove effective; but perfect adaptation and the requisite hardness, as a rule, also mean homogeneity, not always though; yet I feel certain of my position, when I say that it is not only far easier to finish a uniformly dense filling, but that the work can be done in a shorter time, and always in a more satisfactory manner. I know of no more discouraging labor than that employed in attempting to put a finished surface on an imperfectly packed filling.

Where a tooth has been mutilated by disease, or the file and disc, a question often arises, as before mentioned, as to whether the gold shall be allowed to overlap the edges of the cavity, or simply be rounded out from them. It is doubtful whether gold can be made to lay against tooth substance in such a manner as to prevent the ingress of fluids. The thinner and deeper, or thinner and wider the overlapping gold, the greater the doubt and uncertainty. If the diameter of the gold is one-third or one-half greater than that of the cavity, we may be almost certain of trouble in the near future.

The difficulty in making a perfect edge is also greatly increased in these cases, and so it is a safe rule to observe to finish the gold to fit the cavity, and to take the place of an overlapping lid as little as possible.

In shaping, the articulation should be left always in such a condition that the filling should, in mastication, be pressed back into the tooth, not out from the cavity.

As a means of education, I know of nothing

superior to making fillings out of the mouth. Anyone who has not tried it will be surprised at the amount of instruction that can be acquired in this way, and in no other. Any earnest worker who makes the experiment will be astonished to find not only that the operation is not easy, under these simple conditions, but as he aims for perfection, how difficult it is to attain. His edges will remain imperfect, and his powders will scratch, and he will wonder how he ever succeeds in the mouth.

To sum up, in preparing your cavity be careful to avoid deep undercuts or pits, and throw as little strain on the enamel as possible, and make clean, polished edges. In packing the gold, bear in mind that your filling must be homogeneous throughout, perfectly fill the cavity and built up in a series of plains, and in finishing imitate Nature in the high polish you put upon your work, for at your best will you fall far short of her beautiful handiwork. To do perfect contour work requires care and skill and a conscientious regard for all details. With practice and experience one will be surprised to find how often the impossible becomes possible, and the difficult easy of attainment.

Dr. Taft: Mr. Chairman, the paper just read is a very good one. It contains points that ought to be regarded and utilized in the treatment or management of the borders of cavities, and especially proximate cavities, which is one of the most important particulars in the matter of filling. It strikes me that in all instances, the operator should be guided by the kind of material or tissue he is working upon, or rather the character of the material. Some teeth are of such good structure, that treatment for the arrest of decay is more easy and simple than in others. The importance of thoroughly studying the character of the tissue upon which the dentist expends most of his operative skill should always be kept in mind; to know just what he is working upon—whether strong, firm teeth, or those of poor, soft structure. It requires very delicate manipulation to secure the best results. I think this is one of the most important points, and a point that is much overlooked by many operators.

Another point that was emphasized, and justly so, was the perfection of finish which ought to be put on the border of every such cavity. It should be polished or dressed with diamond dust, or anything else that will make a perfect finish. Another point is, the overlapping of gold. We all know there is a great deal of faulty work done in this direction; gold overlapping that ought to be cut away. I think that there should be no more overlapping than there has been cutting of the enamel or dentine. In no instance should gold be permitted to overlap the normal or uncut surface of the teeth.

Another point is the uniform condensation of gold in the cavity. Now we may say it is not of great importance, but it is, for if the gold condensed is defective or imperfectly consolidated, there is always room for mischief. It should be a matter of study, then, to secure the most uniform condensation, the most perfect adaptation, the most uniform condensation of the gold throughout the cavity. Great skill is required, and delicate and intelligent manipulations, to secure good results. As to the welding, skilful manipulation is required; the material used must be in good condition, if gold, it must be properly annealed. Any mistake in annealing is fatal. The gold must be free from foreign substance, and it should be pure, and it must be condensed with proper instruments. I believe that nine-tenths of the instruments used are not as they should be. Those only who have manipulated a great deal can tell you how to do it; that is only attained by experience. It is a process that is difficult to definitely explain. The most direct pressure that can be made on the surface is best; if an oblique blow is given, you will very likely destroy the surface for receiving the gold; the best results are attained by as direct pressure as possible. The paper is full of good suggestions.

Dr. Talbot: Any further remarks? Then Dr. Allen closes the discussion.

Dr. Allen: I wish there was a little more discussion on this subject. I always like putting in contour fillings. I think there is as much conscience required as skill; and no man can do good work unless he puts his conscience into it. I am very glad to have my old friend, Dr. Taft, so kindly bring forward many of the points in my paper, and I appreciate it. I will only draw attention now to one point in my paper, to see if I cannot bring out some more discussion about it; because it is a point about which I have thought a great deal, and I hope with good results to myself. It refers to the face of the teeth. The question I want discussed, and I have not seen any writing about it to any extent, is this question of whether gold ought to be built up overlapping the cavity, or rather the gold shall bulge over the cavity, and be finished off. I take the position, and believe that it is one that is substantiated both in practice and in theory, that the building up of the gold overlapping filling, simply lying against the face of the tube, is a great error. Gold in a plastic condition, if overhammered, becomes springy, and does not take position against the face of the tube that you can work with certainty as being a perfect joint. In contour filling, you hammer it against the side of the cavity, there is unequal pressure brought in pressing it in place, and the gold loses its soft character and becomes springy; and the more you hammer it, the more the springy qualities of the gold are brought out, and it will work away from the side

of the tube, and not lie uniformly and flatly against it. That point is one I would like very much to hear some discussion about, as to the advisability of allowing the gold to overlap the edges of the cavity to any extent, and if any, to what extent. I thank you very much for your kindness in hearing my paper, and for the favorable reception of it.

Dr. Talbot: We will now hear Dr. Andrews' paper on the "Growth of the Cementum."

GROWTH OF THE CEMENTUM.

BY R. R. ANDREWS, M.D.,
OF CAMBRIDGE, MASS.

In the year 1858 Magitot, a French histologist, claims to have found within the follicle of a developing tooth a special organ for the development of the cementum. In 1861 Robin and Magitot made a presentation of the same facts anew. With the exception of these authors, I am not aware that any other authority has recognized the presence of this special organ; while such men as Kolliker, Waldyer, Herz and others have formerly denied its existence. In my own investigations I have not been able to trace it with certainty, although there are appearances in a fully formed follicle of a tissue under the calcifying dentine germ between it and the outer covering of the sacculus that might admit of the supposition of the existence of such an organ. I have noticed this appearance in sections from embryos from the pig and the calf. At a later stage, where the crown is further developed, there is also to be seen infoldings of the tissue at the base of the germ, that may develop into an organ for the growth of the cementum, as stated by Magitot. But in teeth more matured, where the cementum has already commenced its growth, I cannot trace even the outline of a special organ, although I do not consider my investigations to have been extensive enough to warrant me in denying its existence altogether.

Wedl, whose description of the development of the dentine and the enamel is so minute, has but little to say about the development of the cementum. He tells us that, at the margin of the crown, the dental sacculus contracts, and upon its inner surface the formation of the cement is affected, increasing gradually as the formation of the root advances. The lower segment of the dental sac becomes, therefore, the root membrane of the tooth. He believes with Tomes that Nasmyth's membrane belongs to the cement. Again, he states that the dentine and cement are connected together by means of a layer composed of an agglomeration of transparent globules of varying degrees of thickness. The spaces intervening between the latter (interglobular spaces) are irregularly notched and frequently in very close proximity to one another.

He considers that the cement commences outside of this layer, but some of my own sections show it as a dividing line. In describing the methods in which hypertrophy of the cement is formed, he speaks of the various sizes of the corpuscles which form it, stating that many of them have a glistening appearance. Smaller corpuscles are sometimes attached to the sides of larger ones, or are blended with them. Large and small ones also occur separately. These so-called corpuscles are, I believe, globules of calco-globulin, forming by merging into others a layer of calco-globulin, that shall form the matrix of the hypertrophied cement.

Tomes tells us that is difficult to point out any distinguishing structural character between primary bone and that of the cementum. The cells close to the surface of the forming cementum, which were formerly called osteal cells, have now been named osteoblasts. No bone is formed until after the appearance of this osteoblast tissue, and Rollet believes that these osteoblasts are essentially a new growth; they are so distinctly marked off that it almost assumes the character of an epithelium. If we harden a partially-formed tooth in chromic acid, and subsequently decalcify and cut it transversely through the root we meet with the following structures from without inwards. On the outside is the outer part of the sacculus, now the periosteum. Internal to this is a layer to which the name cambium has been given, consisting of roundish cells with processes. These lie in a reticulum made up of cells which give out a small number of homogeneous transparent processes. By the inoculation of these processes a net-work is formed. Between this net-work and the fully-formed cementum lies the osteoblast layer, consisting of much larger cells. As the osteoblasts form a continuous layer and are very numerous it is obvious that only a small percentage of them ever form lacunæ or bone cells, or otherwise retain their individuality. As the process of calcification goes on the outlines of individual cells become lost in the general transparency of the matrix, only a cell here and there remaining as a lacuna. Again, he states that contiguous osteoblasts become fused together by their exteriors, so that their individuality is lost.

Prof. James Tyson, in 1873, writes: Some difference of opinion existed as to the exact tissue which undergoes conversion into cementum, some alleging that it results from ossification of the tooth sac, while others, among whom are Kolliker and Bèale, believe it to originate in a soft stellate tissue, made up of branching and communicating cells, which are found upon the surface of roots of teeth, and within the tooth-sac. This tissue undergoes calcification, spherules of lime being deposited, which gradually fuse and form a transparent, intercellular substance. In

this process not all the cells of the stellate tissue become lacuna of the cementum, but some are obliterated by the deposit, and there are therefore fewer lacunæ in the resulting cementum than in the previous stellate tissue, while the canaliculi are much more numerous than the prolongation of the stellate cells, many of the lacunæ having thirty or forty prolongations, while the stellate cells rarely have more than from ten to twelve. The cementum is more slowly formed than bone, and a more permanent, but probably less perfect tissue; its matrix is harder and more transparent, in this respect approaching the dentine.

Klein tells us that the tissue of the tooth-sac represents the matrix from which the cement is formed; its structure and function are that of the osteo-genetic layer of the periosteum, and that the formation of the cement out of that tissue is identical with sub-periosteal bone.

My investigations show that if we examine the developing tooth, just after the cementum has commenced to form, we shall find that the matrix of the cementum is made up of masses or layers of that tissue, which we find everywhere on the borderland of calcification, between the organic and inorganic substance. This is a tissue which Tomes has said was produced solely by the destructive action of weak acids, but that his conclusions are erroneous is proven by the fact that this tissue appears in sections where no acid has been used. It is a tissue formed by the coalescing of minute, globular bodies, calco-spherites, into globules and layers of a tissue that is called calco-globulin. The minute globules, in forming the matrix of cementum, seem to come from the osteoblasts and form the calco-globulin layer in somewhat the same manner as I have described and pictured in the developing dentine. The smaller globules, by merging into each other, form larger ones. They have a glistening appearance, like fat-cells, are about the size of the osteoblasts, but are not cells, though often taken for them. They have no membrane and are without a nucleus. They are the bodies which Tomes and others say become fused together by their exteriors. Outside of the layer formed by the globules, the developing matrix of the cementum, we see a row of cells, which Rollet stated looked like an epithelium. They are the osteoblasts or cementoblasts, and the granules that have been described in their substance are very minute calco-spherites, which the cells give out to the forming matrix. Tomes has called them osteal cells. They are the same in appearance as those we see around the edge of the developing bone of the jaw. Just exterior to these cells we find roundish, nucleated cells with innumerable processes, reminding one somewhat of a stellate reticulum, only that the stellate character is not so marked. Just outside these we find the connective tissue which is really the perios-

teum. If there exists at this time a special cement organ, it must be formed by this slight amount of stellate tissue which is between the periosteum and the layer of osteoblasts that are against the forming cementum. In preparing my tissue, so as to have it as near life as possible, I made use of the same methods as were described in my papers on the development of the dentine and of the enamel, and I find that the osteoblasts, which are said to be full of a peculiar granular substance, are, when the tissue has been properly prepared, found to be filled with minute spherical bodies, which have a glistening appearance. Across the developing matrix of the cement are found numerous fibres, probably connective tissue fibres, that are also found in developing bone. They were seen and described by Sharpey and are named after him, Sharpey's fibres. They become calcified within the matrix. As the cementum grows thicker we find that the developing matrix is infolding in its substance large nucleated bodies which appear to be connective tissue corpuscles. They are somewhat larger than the osteoblasts and are forming the cement cells, or lacunæ. They have a higher function than the osteoblasts, that is, they are to give nourishment to the matrix, being connected with others by means of canals or processes, of which there are many, some of which run in the direction of the termination of the dentinal tubes, as though connected with them. When enclosed by the developing matrix of the cement, minute, glistening, globular bodies are seen within their outline, or membrane; indeed, it appears as though these minute globules were deposited on the periphery of the cell by the cell itself and here fusing give the cell its peculiar characteristic shape, which is not as regular as that in bone, and is oftentimes very much larger. Their processes, probably anastomose, with the dentinal tubules through the inter-globular spaces of the so-called granular layer, although I have never been able to trace them. I look upon the granular layer itself as a condition caused by an arrest of the developmental process, while the first layers of dentine were being formed. It has its existence solely from the fact that in the first forming layer of dentine the globules of calco-globulin which form its matrix did not fuse together. It is exactly identical to the inter-globular spaces found in the crown. The point that I would emphasize in this paper is that the matrix of the cementum is formed from a secretion of the osteoblasts, and this secretion is a multitude of minute globular bodies, given out against the dentine. In a work entitled "General Biology," written by Profs. Sedgwick and Wilson, they make a statement that the matrix of a tissue is composed of lifeless matter which has been manufactured and deposited by the living protoplasm constituting the bodies of the cells; and,

again, cells may manufacture a lifeless substance which appears in the form of solid partition walls between the cells, or as a matrix solid or liquid in which the cells lie; and, again, the cells are small masses of living matter or protoplasm which deposit more or less lifeless matter either around (outside) them or within their substance. The lifeless matter which is given out by the osteoblasts to form the matrix of the cementum is in the form of these minute globules, and these fusing together form larger ones, which merging form layers of an uncalcified substance that Prof. Harting has named calco-globulin; this is by further calcification to become the calcified matrix. In speaking of the formation of exostosis, Tomes states that at the junction with the root he finds a substance that is dense. It is torn with difficulty, and under pressure slips about between the two glasses. It is gelatinous, osseous matter, and with it may be seen rounded, amorphous molecules. This is a good description of calco-globulin. Tomes says that the cementum is not developed by a direct metamorphosis of the periosteum, but by the calcification of a new growth. Cells are produced, the individuality of which becomes lost in the process of calcification; the interior of the cells seems stuffed with an opaque and dense substance disposed in large granules, among which the nuclei cannot positively be pointed out. The large granules within the cells are really calco-spherites and careful preparation of the tissue will clearly show them. The merging together of these globules forms a layer and this calcifying, layer after layer, gives to the cement the peculiar laminated appearance that is so often seen. It is by no means difficult to trace evidences of this globular formation in the cementum of fully formed teeth; indeed, I have several sections of human teeth that show the outlines very clearly—so clearly in fact that one might call it the interglobular spaces of the cement, probably caused from some arrest in the full development of the tissues.

Dr. Marshall: Mr. Chairman, as I feel I shall be obliged to absent myself, I wish to make a report from the nominating committee, for Chairman of the Section, Dr. Taft, of Cincinnati; and for Secretary, Dr. E. S. Talbot, of Chicago.

Dr. Taft: I would rather that some one else would accept. I do not absolutely decline, but think some one else can hold the position better.

Dr. Talbot: I think it will be necessary for the committee to confer with each other still further, and while they are conferring, we can hear a discussion on the paper.

Dr. Andrews: I understand it is necessary to vacate this room at 5:30.

Dr. Talbot: We have ascertained that is not the case. So we can discuss this paper.

Dr. Taft: I want to make a remark in refer-

ence to this matter. Dr. Andrews referred to what are ordinarily termed globular spaces, and gives the location as between the enamel and dentine.

Dr. Andrews: Not between the enamel and dentine—just within the dentine.

Dr. Taft: I know; I understood you to say this position has been taken by others, that they located the inter-globular spaces in this granular layer, but that is not the location nor the appearance as originally described by Czernack, as recorded by Kölliker. If the structure denominated inter-globular spaces is to be found in the granular layer, then what is this globular structure within the dentine?

Dr. Andrews: The one is like the other, with this difference: the calcified globules near the cementum are small, while in the dentine of the crown they are much larger.

Dr. Taft: We have not ordinarily applied the term inter-globular space to this layer between the enamel and dentine. In some instances there is a very large mass of it, of considerable thickness. Another peculiarity of that layer is, it seems to consist, whether of thick or thin, of mere little globular granules. In some instances there seems to be tubuli, or something of the kind, extending through it to a very considerable extent. I wish I knew more about that than I do, and about the inter-globular spaces.

Dr. Andrews: Inter-globular spaces are found with the globules, in layers, the layers of formation, some near the enamel, others nearer the pulp. In the teeth of some fishes, the whole matrix is globular. In the human tooth, it is an evidence of lack of nourishment while the tooth is forming. The globules do not fuse, they are arrested and calcified as globules, not forming a perfect layer of matrix. The substance between the globules is not a calcified substance. Some teeth have very little, some have no evidence of a granular layer, so-called, others have a good deal. Some have hardly a trace of what we call inter-globular spaces in the dentine of the crown, others will have a large amount. It is an arrest in the developmental process in the formation of the tooth while it is forming a layer of matrix. For some reason, the globules have become calcified while in the globular form, before they have fused together. The tissue of inter-globular space is not fully calcified, while the globules always are.

Dr. Allen: This theory of Dr. Andrews', which I believe he does not stand alone in, is one that I think we should place in the status that the old Scotch law allowed, when a person was tried, and was neither innocent nor guilty—it was not proven. The three structures of which the two substances are composed, enamel, dentine and cementum, are as diverse in their character and structure as any three tissues well can

be. According to this theory of Dr. Andrews, all three of these substances, materials or tissues, that is, the matrix of them, have a like developmental basis.

Dr. Andrews: The lime base of the matrix material, the basis substance, is the same in all. It is the calcified tissue.

Dr. Allen: All three are formed from cells, which have special duties required of them. Enamel is only 2 to 4 per cent. animal basis, 96 to 98 per cent. mineral. Dentine, again, is 30 to 40 per cent. animal, the balance mineral. I have examined a great many of these specimens of Dr. Andrews', and I have endeavored to see exactly as he sees, and I think I do see what he sees; but I don't interpret it as he does, for this reason: The material, whatever it is, the calco-globulin, is thrown out in the shape of little globules, which vary greatly in size and character. The position may or may not be a vital condition. All these preparations of Dr. Andrews' were made with the greatest care, and from sections as little changed in preparation as possible. The calcification was produced by a very weak solution of acid, and every care taken to change the tissue as little as possible; but—and I hope I may be excused in saying so—it is not proven that these are not post-mortem appearances; and a long series of experiments will have to be carried on to prove whether they are post-mortem or living appearances. You do have unmistakable indications of these globular layers; and they are beautifully shown in these preparations. These appearances are not constant; you see them now, and again you don't.

Dr. Andrews: I have been speaking of the matrix substance, not its animal base; that is another matter. The globules are always present in my specimens.

Dr. Allen: But the main point I wish to show is, that I do not see whether this cannot be, in a measure, post-mortem appearances. I do not see why the fluids that have been used in preparing the tissues, the glycerine in which they are mounted, may not have some cause in giving them their characteristic appearance. It is a most interesting point, whether the two kinds of cells that go to make up the formation of dentine, really exist or do not exist, one the fibre form and the other the matrix forming. We often see appearances that would indicate double or dual nature of the cells that form dentine. In enamel it is not so. We do not often treat, and we seldom see, dual character of cells. To be sure, the enamel is so totally different, that the one form could be dispensed with; but in the sement magann it could not be. There we have a large mass of animal matter, and we have a composite structure, dentine.

Now, so far as these inter-globular spaces are concerned, Dr. Andrews specimens were taken

under high power. The inter-globular spaces in dentine are vastly different in size from those inter-globular spaces that Dr. Andrews threw on the screen. Take a tube and make a section of it, and you will find inter-globular spaces sometimes; I should say they would extend across nearly one-tenth of the thickness of the tube. Those globules are much smaller than the average size of the inter-globular spaces you find in dentine.

Now I am not saying that this theory is not true. I believe that the evidence Dr. Andrews offers is very strong and confirmatory evidence. I only say there are still some points open for investigation before we can say proven and adopted. I don't know of anyone in the profession who deserves greater respect than does Dr. Andrews, or who has done more disinterested work; and the results have been certainly most gratifying. I can say this heartily and truthfully; and I know of no one who has given his specimens more freely and generally to others for the purpose of examining them.

Dr. Taft: I wish more attention was given to the discrimination of these two conditions as just indicated by Dr. Andrews. The large spaces within the dentine that are ordinarily denominated globular spaces are very different in size from any condition that is found in the granular layer. In the granular layer these little spheres are granulous and thoroughly calcified. This peculiar structure, abnormal structure, in dentine marked by these lines in a greater or less degree, is defective structure; and then these circles or segments of circles that is within dentine that is not in a normal condition, occasionally you find deep lines running through that, and in some of them no organization of that kind at all.

The globules are thoroughly calcified. The inter-globular space is not perfect, but the globular spaces are perfect. The tissue between the globules is not calcified, but the space between the globules is soft. I assume this matter is clear to Dr. Andrews, but I wanted him to make it clear for me and for all of us.

Dr. Andrews: If you will examine sections of teeth where there are inter-globular spaces, you will find the globules are calcified. In dried sections, the spaces between the globules will show dark under the microscope, in the same way as the tubes do. It is because the spaces are not calcified, and when dry they fill with air. Some of the globules are only slightly attached to the matrix, while others show only a portion of their contour.

Dr. Allen: Do I understand you to say that this is a secretion?

Dr. Andrews: It is supposed that the line in the form of minute calco-spherites, comes from the blood. These pass through the cells, and are seen to be merging together forming larger

globules, or mulberry shaped masses, and these fusing form the perfect layer of matrix, if there is no arrest of development, while they are in this stage.

Dr. Taft: You make the point, it was arrested in development?

Dr. Andrews: Yes, when inter-globular spaces are found.

Dr. Taft: You mean that the environments are not perfect?

Dr. Andrews: Yes sir.

Dr. Marshall: Mr. Chairman, the nominating committee beg leave to report Dr. J. Taft of Cincinnati for Chairman, and Dr. E. S. Talbot for Secretary of the Section.

The report was unanimously adopted.

Here the chairman calls on Dr. Grady to read his paper on "The Use and Abuse of Dental Charity."

DENTAL INFIRMARY PATIENTS: THE USE AND ABUSE OF DENTAL CHARITY.

BY RICHARD GRADY, M.D., D.D.S.,
BALTIMORE, MD.

My object is to call attention to the abuse of dental charity, to illustrate its magnitude, and to protest (as every honest and independent man who wishes well to the profession and its respectability should) against the looseness with which dental colleges dispense their so-called charity—to "condemn the fault and not the actor of it;" for silence would give an indirect connection to practices which are lowering the profession in public estimation in the tendency of dental infirmaries to pauperize the people and to defraud dentists of rightful fees. So, judging of the proprieties and obligations of my position, I place the statements—dental infirmary patients: the use and abuse of dental charity—together, and propose to consider them in connection, because the evidence in regard to them constantly mingles.

You, gentlemen, familiar as you are with recent medical literature, if not appalled at the rapid growth of the dispensary evil, fully realize that it is an evil, that it is taking the means of livelihood from many deserving men, that it is growing, and that it must be combated to be kept within proper bounds.

The sorrows of our cousins across the ocean have been told you in the medical press. "The dispensary abuse in other lands," "the startling excess of medical charity in Edinburg," "the abnormal growth of the out-patient department at Cambridge," "the great and urgent question of hospital reform" in Birmingham where the out-patient of hospitals "have advanced in 20 years—1867 as compared with 1887—from 67,000 to 166,000," etc., have been commented upon. "Al-

most one-half of the people of Edinburgh, Scotland, receive their medical advice gratis. (The population is little over 236,000, and 103,095 dependent on charity for medical advice!) Nor is this all. The number of persons who in any year actually avail themselves of such aid must of necessity be smaller than the total number who would do so were they forced by sickness or accident; and it looks as if more than half the population were in the habit of expecting medical treatment gratis."

"In the city of New York wealthy hospital magnates are teaching the people the lessons that they have already learned in Edinburgh. In New York the amount of free work done in hospitals has increased 90 per cent. in the last decade. In time the hospitals may become as much an enemy to the general practitioner as the dispensary is. A western medical editor, who, last summer, visited some of the hospitals and clinics of the great metropolis, is quoted in the discussion of the question, "Should a poor man study medicine?" as saying: "What was most striking, outrageous as it is, was the great number of well and fashionably dressed, evidently well-to-do people, both male and female, who applied for free treatment. At the ——— on Tuesday, August 12, there were 568 patients, and judging from their appearance we venture to say that three-fourths, at least, of them were abundantly able to pay for private medical service. We have, of course, heard the numerous complaints among the New York physicians on this account, but we were not prepared to witness the spectacle presented there of gayly-attired, semi-aristocratic humanity going in droves, petitioning for free prescriptions, free medicines. The profession in New York would be justified (he says) in arising in emphatic and effectual protest against such wholesale diversion of their revenues."

Why do I recall these things? Not simply to remind you that this coöperation of the medical journals with the medical profession is an excellent example to the dental journals and the dental profession, but rather to emphasize the fact that what is true of the medical profession is, to a considerable extent, also true of the dental profession. As far back as March, 1889, I wrote to the *Dental Cosmos*, to ascertain if anything on "dental charity" had ever been published. The reply of the editor was: "I do not recall that the subject has been discussed in any dental journal, and I feel quite confident that it has not been in the *Dental Cosmos*. The subject is a delicate one, because it concerns a natural but sometimes unprofessional rivalry between dental schools in the same city."

It is an encouraging sign of the times that, as Baltimore is the city in which regular collegiate instruction was first given in dentistry, so Baltimore dentists, appreciating that it is but seemly

for the profession to avoid and suppress, as far as possible, the rapidly increasing source of pecuniary loss through a channel of their own making, have become the pioneers in the reform of indiscriminate service in dental college infirmaries, which reform will, in no small degree, benefit the dentists in that city and in other cities.

Concerted opposition to dental infirmary abuse has been organized in Baltimore, and the Maryland Dental Protective Association, composed of a majority of the practicing dentists in that city, not including those pecuniarily connected with dental schools, came into existence in February, 1890, the object of the organization being to regulate the administration of dental charity so that the greatest good may come of it. The members, believing that the impulse must come from the dentists rather than the colleges, are doing what they can to obtain an abatement of the evil which is making such inroads into their practice. Nothing, thus far, has resulted from the movement, except the adoption of the following resolution:

"That each of the dental schools be requested to place in the infirmaries (near the entrance) record books, in which shall be printed in bold type on each page, 'For the poor only,' and in which shall be entered the name and address of all applicants for dental services. After such registration, each applicant shall receive a card, also headed, 'For the poor only,' if he or she admits inability to pay the usual office fees; all others shall be rigidly excluded from infirmary privileges. This card shall be retained by the patient, and presented at each visit, and until the completion of all necessary services; when the card (endorsed by the operating student with his statement), shall be returned to the demonstrator and placed on file. The record books and the cards shall be open for public inspection at all reasonable times."

The President of the Association has also visited the Mayor of the city, to request that no appropriations be made to the dental schools for 1891, unless in the contract there be included a provision that, 1, all applicants for dental services shall be registered; and 2, that the record books shall be open for inspection. Appropriations of \$400 and \$500 had been made in 1888 and 1889 to one of the dental schools, "for supplying medicine to the indigent sick of the city of Baltimore."

In what follows, I wish it to be understood that I have no reference to any special college. My remarks, I think it not improper and possibly not unimportant to say, are addressed to the system generally. Many of the facts are calculated to arrest the attention and engage the study of the best men in the profession.

Believing that every reform was once a private opinion, and acting upon the advice of Emerson, that "that statement only is fit to be made public which you have come at in attempting to satisfy your own curiosity," I, judging it expedient to gather light from quarters deemed trustworthy, wrote to deans of dental schools, to determine whether dental college infirmaries truly deserve

the designation of charities. The general result of the inquiry confirmed the impression that there is an enormous abuse of so-called dental charity by the almost reckless admission of all comers, and that the practice of some colleges is large and pecuniarily profitable.

As no man's personal rights are in the issue, I give you some of the information elicited as to infirmary charges and infirmary practice:

1. "Our infirmary privileges are extended only to those unable to pay the usual office fees (all others are rigidly excluded); gold fillings 75 cents to \$2.50, amalgam and other plastics 25 cents to \$1, vulcanite (full upper or lower) \$5.50, gold or continuous gum \$25; no record of charity patients to whom relief is extended without fee other than extractions and pathological cases;"
2. "The charge made is intended to cover actual expense of materials used, and whatever may be used in a charitable way; there is usually a surplus of receipts over expenditures; minimum charge for filling with gold 50 cents, for dentures \$5; these amounts vary of course if a larger quantity of material is used or in the case of dentures being made on metal bases;"
3. "The dental college charges simply for material used in plugs and dentures and tries to avoid doing for people who are able to pay regular dentist;"
4. "We average about 8,000 patients of all kinds yearly; charge for gold fillings and other work about what material costs, estimating rather over than under, as we can't afford to lose by our good works;"
5. "The fund we collect from our clinics amounts to about \$5,000 per year of ten months, which we are in operation;"
6. "Charges are slightly more than cost of material; we aim to have the infirmary self-supporting;"
7. "We try to have the charges for material used cover the waste and as much of the running expenses of infirmary as practicable;"
8. "Gold for about 1,000 patients, for which a profit is charged; make no distinction in patients;"
9. "No regular tariff for services; endeavor to discourage well-to-do, by making charges higher than in office;"
10. "Charge for gold filling about one-half what dentists charge;"
11. "Our purpose is to make infirmary self-sustaining," etc.

The time-work—the only legitimate work—of dental colleges—should be to educate students for professional life, to perfect the professional education of the dentist. But this preliminary training should not be used, as it sometimes is, to lower the dignity or emoluments of private practice. For pecuniary interest, some faculties attract as many students as possible (over 3,100 were in attendance at the various dental colleges of the country for the session 1890-1891) whom they send forth in the spirit of rivalry into the ranks of the profession without a thought that the means of subsistence for these men is diminished by dental infirmaries taking patients which these

graduates should have, that having raised up these men to professional life they have the further duty not to pull them down, and that they are warring upon the livelihood of their professional brethren with the inevitable result of all active competition—lower prices; with the prospect that, as the ranks become more crowded, the competition must become keener. Is it any wonder, then, that men often lose heart after struggling for a time against so powerful and so unscrupulous a rival as every dental college infirmary is, whose anxiety for abundance of clinical material is so pressing that there is no discrimination, or hardly any? and that men of talent and respectable professional ability are forced to adopt rates that will in a measure compete with clinical fees in order to secure at least a moderate share of practice, or be driven out of the profession to find support in some other occupation for which they are wholly unsuited by reason of long years devoted to professional labors? Have members of the dental profession no feelings which influential dental colleges are bound to respect?

More than 50 years ago, as you know, the *first* dental college was founded. It was the purpose to give the institution a high character at the start. After it had become necessary to establish an operating infirmary, "for the benefit of the students," this announcement was published:

"There exists abundant opportunity for practical instruction in the Dental Infirmary attached to the institution. The appreciation and consequent demand of such operations as are here performed is steadily increasing among the indigent of our city. It may be necessary to add that these operations are not performed by the professors in the presence of the class, but by the students themselves under the immediate eye and direction of their instructors. In fine, the object of the institution is to perfect the professional education of the dentist, which may or may not have been begun under some competent private instructor and which, it is recommended, should be pursued during the summer vacation in some dental office."

Has the stamp of character the infirmary then received, endured? Have the purposes of the originators of the dental infirmary, who started it not as a money making experiment but for the benefit of the students and as a humanitarian agency, been perpetuated in all the dental colleges which are pleased to acknowledge their origin? Are "operations performed among the indigent" only? Are dental colleges actuated solely by a desire to do good to the very poor? Is attendance at the dental infirmary taken by all the patients as a confession of poverty? Is it customary for students to be found "during the summer vacation in some dental office," or are they to be found at the college filling teeth and

making plates for the pecuniary profit of those who, in the language of students, "Run the infirmary for what they can make out of it?"

The origin of the dental infirmary has been told you; the evolution of the abuse can readily be traced.

1. "Operations among the indigent"—"all expenses borne by college."

2. "Students have the privilege of operating upon their own private patients."

3. The natural development has been that services have been rendered infirmary patients who could pay a proper fee; that "during the sessions, the operative and mechanical departments are now so well patronized, that every student can obtain as much practice as it is possible for him to attend to;" that "the clinical material is abundant, there being an excess of patients;" that "*the practice for dental students* has increased to such an extent that all the students, during the past session, have had an abundance of practical work, in both operative and prosthetic dentistry—the record books showing to the credit of many of them *hundreds* of gold fillings inserted for infirmary patients, besides other operations. This means for practical instruction has already assumed such large proportions that the supply has been beyond the needs of the large classes in attendance during the past sessions."

That the competition of some dental college infirmaries affects to an appreciable degree dentists injuriously, will be obvious to every reflecting person, at the bare mention that "about 25,000 patients are attended to yearly" by one dental college, and "on an average for nine months in the year, relief is extended to about 100 patients a day" by another; that one dental college which was "extending relief to more than 2,000 charity patients" in 1889, reported next year (1890) "more than 10,000 of such cases," and another which reported in 1889 "the charity patients number 4,312," in 1891 (two years later) gave the number of cases "12,000 or 15,000." None of these are located in the great metropolis whose college of dental surgery reports only about 6,500 patients are treated annually, (possibly because) "we charge for the material used in all branches of dental surgery."

This competition is most onerous to the dentists of least income, and to the practitioners who are struggling against the odds of cheap dentistry in an effort to maintain an honorable position, and eke out of their labors sufficient income for a respectable living. The dental infirmaries being open to all classes and conditions of men and women who desire low-priced services, few, if any, questions are asked, as long as the charges are paid, no matter how elegant and costly the habit, nor how many jewels displayed. This pernicious example of cheap dentistry is an injustice to those dentists who resist mercenary competi-

tion, and endeavor to render their bills in conformity with standard fees.

Are there not poor enough to supply clinical patients without encouraging the well-to-do to degrade the profession by responding to the enticing and seductive advertisement, "Many of the operations are performed free of charge, and all others at the cost of materials only," or the knowledge that "during the first two months of the session we furnish all materials to patients free of cost," although it may be said in excuse of the work done for them, "The operations are faulty and but the handiwork of students?" Is it not true benevolence and sound policy to remove, if possible, competition from those least able to bear it? If fair-minded men think so, if the faculties of the dental schools think so, then let the welfare of the whole profession supersede and extinguish the selfishness of the few.

A dentist who would endeavor to obtain practice after the model of the pretentious dental infirmary announcement (which appeals not in vain to the large number of persons who prefer quantity to quality)—"free to all—all operations known to modern dentistry performed in most workmanlike manner—gold foil and artificial teeth at actual cost—amalgam or silver, white, tin and gutta percha fillings free—this is the first time such an opportunity has ever been presented to every one to save those important organs (the teeth) free of cost—old and experienced demonstrators in charge—the same decorum will be observed as in private office, etc."—would be accused of unprofessional conduct, of acts unworthy the lowest grades of the profession, and set down among his fellows as unprincipled, a professional outlaw fit to "send to Coventry."

But, it may be asked, if a corporation of dentists may publicly advertise, why should a private practitioner be debarred? Should not dental faculties hold themselves amenable to professional laws, customs and courtesies? Is the sense of personal responsibility and personal honor depressed when the individual dentist is merged in the abstract entity of a dental corporation? However painful it may be to admit, it cannot be denied that methods which are legitimate for a dental college are not improper for the individual dentist, although claimants for public patronage may not see the question in this equivocal position after they have worked themselves into dental college faculties, by favor rather than merit, and thereby converted the dental infirmary into an ally instead of a rival. That, say what you please, is the plain English of the matter, and it may as well be spoken.

But the effects of the practice are not worse than the statements in the advertisements. One of the most pregnant counts in the indictment against the dental college infirmaries is that they advertise "gold foil and artificial teeth at actual

cost," when really the cost to the colleges for artificial teeth is absolutely nothing, the manufacturers "furnishing teeth to the infirmaries without charge, which teeth are sold in plates at (say) 2,000 per cent. above the cost of material used, and the gold foil is sold at a profit of 100 or 200 per cent. Dental colleges should give an equivalent for the fees they demand; to do *more* is charity, *less* is fraud.

Lest it should be thought I am making statements to suit my argument, let me quote what those think who ought to know best, from the opportunities of observation or experience. The views expressed by the gentlemen are creditable to their sense of justice, and will have such weight with the membership of this Association and with others as they are entitled to.

Dr. Shepherd, President Massachusetts Board of Registration, whose caustic criticisms are yet fresh in the minds of readers of dental literature, says:

Suppose one college furnishes only No. 3 gold in the infirmary, and sells each sheet for 70 cents, making a profit of \$60 per oz., and another college furnishes No. 4 gold, and sells it at 40 cents a sheet, making a profit of \$11.40 per oz., would it not be reasonable to infer that the former was run more for profit, and the latter more for the advantage of the student?

Has the infirmary answered its purpose when it has been successfully run as the Cheap John shop? Some colleges have sixty or seventy chairs. How many demonstrators are there present all the time? I ask any one who has had experience as demonstrator if he does not consider that he has been handicapped as an instructor by having too many operators to look after? Is it a rule in every college that no student shall ever commence the insertion of a filling until the cavity has been pronounced properly prepared by the demonstrator? This would seem to be a reasonable rule.

Are the demonstrators always selected for faithfulness and competency? Is a man who graduates one year generally competent to instruct a student the next year, to be the arbiter as to the how, what and why of the multifarious and complicated conditions that are constantly arising? Such young men, without practice, can be hired cheap. But does the college fulfil its contract with the student by having young and cheap instructors, in the infirmary least of all places, though the professors may divide several thousand dollars apiece each year?

The testimony of Dr. David Genese, who holds official position in two dental schools, is:

It is well known that persons amply able to pay (occasionally persons of known wealth), claim the attention of the students, and needed charity kept so long waiting that they depart or do not get the work done, as the charges are sometimes as much as a young practitioner will make. Where is the charity? and how does the dental infirmary compare this with only "cost of material?"

No student should be allowed to appoint time for people to visit him at the institutions. Every patient should be first seen by the demonstrator, and the work given in rotation to students. The name and address, and occupation of the applicant should be obtained, and if found able to pay, should be referred to a dentist, and not, as at present, charged full fees to go into the pockets of the professors and demonstrators.

Dr. Ferd Groshans, a demonstrator, is of this belief:

From personal experience at the dental infirmary, as student and assistant, I could cite cases of patients who were able to pay, and had their teeth filled and plates inserted, to their own disadvantage, as well as to the injury of the science of dentistry, both of which are due, in my opinion, to the want of a larger number of instructors, as well as to the inexperience of the new beginners. I think a less number of patients would be sufficient, and of more value to the student, if the instruction would be more of a personal supervision and more constant by the demonstrators in charge. I do not think a student should be left so much to himself as is the practice at present. The infirmary practice, as at present conducted, is detrimental to the patient, student, college, and the profession in particular, to say the least, and not considering the practitioner who must live by the legitimate practice of his profession.

These views a Vice-President of the National Association of Charities approved, and added: "We want fewer unworthy applicants, and a better service in the dispensaries."

Dr. J. L. Asay, of California, writing on "the pernicious effect of dental college clinics," says:

That such a condition exists was, to me, made apparent during my visit to the larger cities of the Atlantic coast, last year, but was not confined to any particular dental school. I found it, however, to predominate in Philadelphia, where there are no less than three dental colleges. It may possibly be that I observed this state of affairs more in that city than in other places, from the fact of my larger acquaintance there than elsewhere, it being my native city, and former residence for twenty-seven years, hence, other localities may furnish equal grounds for comment.

During the visit to which I have alluded, I frequently heard old practitioners complain of college operations and their fees. I heard men and women of good circumstances and comfortable incomes congratulate themselves and each other upon how cheap they had got their teeth filled or plates made at the dental college.

He continues:

We may rail against gas offices and bucket shops; five dollar sets of teeth, and "teeth plugged to last for life, for 25 cents," without avail, so long as we countenance the pernicious example of cheap dentistry and low fees by our institution of dental learning, to those who should be compelled to seek the services, if any be needed, of the regular practitioner, and pay a price equivalent to the time occupied and the skill employed.

This expression is confirmed by an official in Philadelphia, under date of April 30, 1891, who writes:

In this city, with its three large dental schools (having in attendance over 700 students during the last session) actively competing for patronage, the evils of indiscriminate charity are seriously felt by a large number of worthy practitioners. Such charity certainly tends to cheapen the services of the dentist, and in many cases causes young graduates to resort to questionable methods of obtaining a remunerative practice. The question is of vital and timely importance.

In conclusion, what is the duty of the hour? What, it may be asked, do members of the dental profession propose for the evil which they allege to exist so much to their prejudice and detriment? Is it to close the dental infirmaries? Not at all, except, possibly, during the vacation when no lectures are delivered, because in our present social condition the dental infirmary may

be necessary (I will not say necessary evil). They suggest a cure more humane, more salutary, more manly, more worthy of them. It is that dental infirmary privileges be extended only to those unable to pay the usual fees of dentists because it is believed that the practice of dental schools in throwing open their doors to whoever may apply, injuriously affects both the public and the dental profession. (The testimony upon this point is so honorable to the dentists of Baltimore that special attention is invited to it, as it has been affirmed and re-affirmed by members of the Maryland Dental Protective Association, and is in fact the sentiment that led to the organization).

Very true, you say, but how is it to be done? If a line could be drawn, where would you place it? I suggest the following for consideration, as possible remedies; other thinkers may be stimulated to supplement what has been omitted. Oneness of aim does not imply identity of means.

1. Go back to the practice of the time-honored pioneer—an operating infirmary “for the benefit of the students”—operators “among the indigents” only “by the students under the *immediate eye* and direction of their instructors”—“all expenses borne by college.”

2. Let no “students have the privilege of operating upon their own patients (private) during the sessions” either at the college or at their homes.

3. Provide for dental infirmary privileges to persons recommended by dentists, or by some inquiring agency, familiar with the circumstances of applicants, similar to the Charity Organization Society, of Baltimore.

These are simple suggestions, and it only remains for the dental colleges, more especially rival institutions in the same city, or those which aim to “have the infirmary self-supporting,” or “have a surplus of receipts over expenditures,” to put them in practice. Even if it had been found difficult to devise remedies, the calling of public attention to the evil would have been useful.

Some dental colleges, to their honor be it said, already discriminate; as for instance the University of California College of Dentistry whose rule is “Infirmity privileges are extended only to those unable to pay the usual office fees” (all others are rigidly excluded); or the Philadelphia Dental College which “tries to avoid doing for people who are able to go to regular dentists;” or the Indiana Dental College, which uniquely “endeavors to discourage well-to-do people by making charges a little higher than those ordinarily made in offices;” or the University of Maryland Dental Department, “whenever it is possible to discriminate, the patients supposed from general appearance to be in good circumstances (as we have no other means of judging as to financial ability) are rejected in favor of the poorer classes of patients. We shall continue to

pursue this course as an act of justice towards the dental practitioners of the city of Baltimore and the State of Maryland.”

The interests of the dental profession and of the dental colleges are really identical, and they should be made practically so. At present there is a combat between those with whom unanimity of purpose and honesty of intention should prevail. Each sets the other at defiance, and as a rule, there is little kindly feeling and few friendly acts on either side. It would be otherwise if the graduates of dental schools, instead of having to suffer from acts prejudicial to, or sometimes injurious, to their interests, were made the objects of a generous, parental care. Such consideration would dispel antagonism, and the charity of the public could be confidently appealed to, with the support of the profession, notwithstanding there would be (apparently) a falling off in the number of patients at the dental infirmaries.

This is an age of associations, hence it is desirable that the State societies be formed which shall coöperate in protesting emphatically against the abuse of dental charity and in taking effectual measures for its correction, so that in case of application for State or municipal (financial) aid on the plea that “the faculty are receiving now scarcely any remuneration—they ask that they be relieved from the cost of the very charitable institution which they have necessarily connected with the college;” or “the faculty find themselves compelled to ask aid from the State—they are not willing that the institution shall perish without giving the State an opportunity to preserve it,” it may be made known that no such assistance is given in the cities of Boston, New York, Philadelphia, Washington, Chicago, Indianapolis, Cincinnati, Louisville, Minneapolis, San Francisco, by the taxpayers to the dental schools.

The paper was discussed by Dr. Taft of Cincinnati, Dr. Clara McNaughton of Washington, Dr. J. J. Williams and R. R. Andrews of Boston and E. S. Talbot of Chicago, after which the following resolution was unanimously adopted:

Resolved, That this Section would suggest to the National Association of Dental Faculties, the importance of some action towards correcting any abuses of the charities of infirmaries or schools.

Dr. George W. Whitefield read a paper on

PATHOLOGICAL CONDITIONS PRODUCED BY GALVANIC ACTION BETWEEN DISSIMILAR METALS IN THE CARE OF TEETH.

and then illustrated some of the points in his paper by an exhibition of electrical apparatus.

To arrest the causes that destroy the teeth,

fillings of different kinds have been and are being used to repair the loss of continuity of tooth structure, to protect exposed parts, and restore the contour of the organ. Prominent among these filling materials are gold, tin, cements and amalgam, or, as it is sometimes called, silver. It is composed in varying proportions of tin and silver, with a small amount of gold or platinum amalgamated, as the term implies, with quick-silver. There are also amalgams of copper, and some containing zinc.

In a general way, I will now introduce the subject of this all-pervading mysterious form of vibration we call electricity. Different qualifying names are employed to designate the kind of electrical manifestations, as magnetic, frictional or static, galvanic, voltaic or dynamic and thermal electricity.

We find that all molecular disturbances give rise to disturbed electrical equilibrium; all motion tends to produce this condition. We notice the result only when the conditions are favorable, that is, when the conditions are such that the equilibrium is not too easily reestablished.

Electricity is termed positive (+) when it has force to impart, negative (—) when it will require such an amount of electrical energy to restore the electrical equilibrium. The difference of electrical conditions is termed the difference of potential.

Difference of potential is a difference of electrical conditions, by virtue of which work is done by the electrical vibrations in moving from the point of higher to that of a lower potential, and is measured by the unit of quantity of electricity thus transmitted.

The passage of electrical vibration from the point of higher to that of lower potential, is termed electrical current, and the bodies along which they pass are conductors. The opposition to the passage of the current is termed the resistance.

In order to understand the action of what is called electric current, I will give the familiar illustration of two reservoirs of water connected by a pipe. The electric current may be likened to the flow of water through this pipe from the higher to the lower level. The unit of current strength, also called the rate of flow or intensity, is the ampère. In the illustration we would say the water is flowing through the pipe at the rate of one gallon per second. In speaking of the electric current, we would say it has the strength of, say one ampère.

The unit of electromotive force, also called electrical pressure, or tension, or difference of potential, is the volt. In the illustration the head of water, or the difference between the levels A and B, is similar to the electromotive force.

The unit of resistance is the ohm. Resistance

may be compared to the friction the internal surface of the pipe offers to the water. It follows that the more cross-section the less friction, and the less cross-section the more friction, for the same volume of water flowing through the pipe in a given time.

Conductors are good or bad as they convey or resist the passage of the electrical current; different metals vary in their conductivity, silver and copper being high in the scale, while German silver and steel retard the current; moisture is a good conductor, while glass, kerite, rubber and dry air are among the poorest conductors; the resistance varies with the length of the circuit, the conductivity and cross-section of the conductors.

As the current is the same strength throughout its entire length, it naturally follows that the larger the conductors, other things being equal, the less the resistance, and on the other hand, the lessened surface or poorer the conductor, the lessened current and reduced activity of the battery. When the current is too great for the conductors the wave length is shortened to that of heat, which varies according to the current and the conductors. The wave length may be shortened to that of light vibrations so that the conductors may glow as in the incandescent lamp or cauterizing snare. Heat generated in this way is now employed in electric welding, and for the fusing of metals requiring a high temperature, such as platinum, iridium, etc.

Magnetism derives its name from the place where magnetic ore was first found—Magnesia, Asia Minor.

Frictional or static electricity, is of but little interest to us as a profession, although often, in a dry atmosphere, it may be a very annoying companion by the dental chair, when each movement of the operator produces by friction a difference of potential between the operator and the patient; then if the discharge is by way of an instrument to a filling, or moisture in a cavity of a tooth, the result, to say the least, is unpleasant, and often quite startling if the patient, by jumping, upsets the instruments.

Frictional electricity is to galvanic electricity, what a red hot needle would be to a large, moderately heated crow-bar; the crow-bar contains more heat than the needle, but one has a volume, the other intensity. Frictional electricity is so intense that it will jump through air, the length of the spark being governed by the intensity of the current.

Galvanic electricity, on the contrary, will traverse the circumference of the globe, rather than leap a short space. Galvanic, voltaic or dynamic electricity, is the particular manifestation of this force, most interesting in a practical way, to the dentist. The current derived from the battery is called galvanic or voltaic, in honor of the experimenters who, less than 100 years

ago, discovered the method of generating and collecting the force through chemical action. It is this manifestation of electrical energy that is employed in the arts, consequently the name dynamic.

Where the extensive use of electricity is required, the dynamo is employed for economical reasons.

Batteries consist of positive (+) and negative (—) elements, immersed in an exciting fluid, or fluids. The fluid employed varies according to the construction of the battery, and kind of work to be done, being acid or alkaline; though even pure water will generate a current, if two metals are immersed in it where one metal is more readily oxidized than the other. (Note the fact that action would take place if the elements were composed of two samples of amalgam, if one was composed of less oxidizable metals than the other).

The positive (+) element of the battery is the one on which the exciting fluid acts, that is, the fluid destroys the positive (+) element, molecule by molecule, while the negative (—) element should sustain no loss of structure. If the negative (—) element is acted upon by the fluid, counter currents are generated which interfere with the usefulness of the battery. I spoke of the resistance of the conductors; the fluids of the batteries impose resistance, termed the internal resistance. The electrical energy of a battery is the energy of the current, less the internal resistance, and the resistance of the circuit. The resistance both internal and of the circuit, modifies the action of the battery. If the elements are connected with wire of sufficient size to convey the current, the electromotive force will be reduced in proportion, as the length of the wire is increased, or the size (cross section) of the wire is reduced; while, if the elements touch in the fluid, the action is most violent, and the batteries soon become polarized, that is, the surface of the elements become so changed that the fluid ceases to affect them or the fluid becomes so saturated with the waste product of the combustion of the positive (+) element that action practically ceases; unless provision is made for it by having the fluid constantly renewed, as in some kinds of batteries designed for constant work.

When the circuit is opened shock is felt, if the current is of sufficient strength; this shock is the result of the magnetic energy being suddenly discharged; different devices are made use of to produce this result, such as the induction coil, constructed with a vibrator, which rapidly makes and breaks the circuit; an example of this is the medical battery, and the Ruhmkorff coil; the current produced in this way is called the Faradic.

Now, to apply the foregoing to the battery formed by dissimilar metals in the mouth, where

the fluids of the mouth are the exciting media, gold will be the negative (—) element, as the fluids of the mouth have no action on this metal. The positive (+) element is the baser metals, whether used separately, as tin, or, as most commonly, the combination of mercury with tin, silver, zinc and copper, as in the amalgams in use.

With gold and tin to form the voltaic pair, the base metal soon becomes coated, and the current practically ceases, but with amalgam, the mercury performs the same office in the mouth that it does in the laboratory; it presents the metal in a form that is easily acted upon by the exciting fluid.

We always have good conductors in the fluids of the mouth, containing, as they do, mucus and various earthy salts, while often the fillings touch in the same mouth, or as approximal fillings of gold in one tooth, and amalgam in another.

We always have good conductors, although the resistance varies in each individual case, according to the character of the secretions, or the situation of the fillings.

The action will vary according as the conditions are changed. Naturally, where food is left between the teeth, to decompose, the acid resulting from such fermentation will form a more exciting medium than normal alkaline saliva. Where a filling is left rough and jagged, overhanging and irritating the gums, it presents an exaggerated surface to be acted upon; besides, by irritating the gums, it causes a secretion from them that forms an excellent exciting fluid. This is, unfortunately, the too frequent result of careless operating.

Now, what of it? Is this only theory? Are these statements founded on scientific facts? Can they be established by proof? *The Western Electrician* of February 11, 1888, says, in reference to a talk I gave before the Chicago Electrical Club:

"Dr. Whitefield, before the Chicago Electrical Club Monday evening, succeeded in settling a question that has been in dispute among dentists, as to the electric action of amalgam and gold fillings in the same tooth, or even in the same mouth.

"That a current was generated by the amalgam and gold fillings when placed in water, even when they were insulated from each other, was conclusively shown by bringing a galvanometer into circuit. The point is one that may be combated, but the evidence produced by the galvanometer cannot be controverted."

Now if there is galvanic action, what harm can it do? Let us quote from an article on amalgam in the November *Dental Review*, 1887:

"Now the question arises: Shall we ever use amalgam and gold in the same tooth, and if so, why? and if not, why not? There has been such varied teaching in the past in regard to this subject, that it is time the old errors should be ex-

ploded, and scientific teaching presented to our students of to-day. The old way was to put both amalgam and gold in the same tooth, if it seemed necessary, but never let them touch each other, or grave results would follow. After seeing such methods pursued for a term of years, we find that, in spite of the teachings, grave results did follow, which ultimately resulted in the loss of the gold filling, while the amalgam remained comparatively sound, or, rather, the tooth structure surrounding the amalgam filling."

This is correct—but to go on and see the writer's following statements:

"We have found that if the two metals touch in the electric battery, there is no longer a current, it is dead, no shock is produced, and it is just the same when the metals are in the tooth in the presence of an acid, as it is out of the mouth in the laboratory. Therefore, we found, first, from an unpleasant experience, and later from theory, that if amalgam and gold are placed in the same tooth, they should have an uninterrupted communication, should be in complete apposition, so that no electric or galvanic action can take place, because they touch each other."

Let us consider these statements, and see if they harmonize with the laws of physics. Now, if the elements touch (the fillings), there is practically no resistance in the circuit, consequently the battery's action is most violent, up to the capacity of the battery to generate current.

The writer says no shock is produced. He is right; the current flows evenly through the short circuit, so the equipoise is practically maintained, and shock is produced only when the current is interrupted, when an accumulation of energy is suddenly discharged.

To be fair, I will essay to point out what has misled my friend into making these rash statements.

If gold and amalgam touch in the same tooth, there is practically less destruction around the gold filling. This is easily explained, as the galvanic action is so violent that the surface of the amalgam filling is soon destroyed; that is, all the baser metals are consumed from the face of the plug, leaving the silver, gold or platinum of which it is composed, on the surface, which practically changes the amalgam to nearly a silver surface, thus raising it to nearly a negative metal, while beside this, the coating protects even the surface of the silver.

This statement holds true with regard to very old plugs of amalgam; their surface is no longer amalgam, it is negative metal.

But at what fearful cost are such old fillings raised to the dignity of negative elements.

We will now note some of the harmful phases of this subject.

First: Galvanic action has a tendency to accelerate the blood flow, producing hyperæmia and hyperæsthesia, and in some cases violent ner-

vous phenomena. This is especially the case where, from the situation of the fillings, the energy is accumulated, then suddenly discharged, producing shock, as each can demonstrate by touching a bit of zinc or the blade of a penknife to a filling in your own mouth.

Second: The current is generated from all parts of the elements that come in contact with moisture, and are not protected by a coating. The portion of the amalgam filling that is protected by tooth structure becomes so coated that there is practically no action except on its exposed surface. On the contrary, gold remains bright on all its surfaces, and as moisture pervades the whole tooth, no matter how well the filling is inserted, moisture will reach it by way of the inter-tubular spaces, consequently electrolytic action can take place from all portions of the gold elements, naturally causing considerable destruction around the gold filling, and this is not all electrolytic action takes place. Among the commonest elements found in the mouth is chloride of sodium (salt); galvanic action readily breaks up this compound, the chlorine liberates oxygen and unites with the hydrogen of the water, forming hydrochloric acid, and leaving the oxygen in its most energetic state (other acids may be formed in this way, such as sulphuric, nitric, etc.). The electrolytic action, and the acids thus formed, are sufficient to roughen the surface of the teeth to give lodgment to colonies of "microbes."

Is this all? No. Chlorine, in its nascent state, will readily unite with the mercury of the amalgam, and the chlorides of mercury may be formed in sufficient quantities to produce symptoms of mercurial poisoning in those susceptible to its influences. These salts of mercury may also explain the immunity from decay of teeth stopped with ill-fitting amalgam plugs, the germicidal effects of the mercury being sufficient to prevent colonization by microorganisms, and consequent destruction of the tooth.

The oxygen might, from peculiarities of the individual case, unite with other salts than those of the teeth, and the same with the acids. We all know that the neglect some mouths get would be total destruction in others. The elements that usually produce decay would seem to be inert in their case, and the same condition undoubtedly explains why electrolytic action that would destroy in one case is apparently harmless in others, although such cases are in the minority.

The usual result of placing amalgam in the back teeth, while gold is placed in the front teeth, of children, will explain why the gold fillings have to be renewed so often; also, that in the electrical action is a clue to the oft-repeated tale brought to us by the laity, that amalgam stands better than gold, as the amalgam still remains, and the gold fillings, that have been replaced several times, are loose again.

If amalgam must be used, use those grades that will readily become coated, as the coating will reduce the galvanic action, protecting the plug from the fluids of the mouth, except where attrition and brushing keep them bright. Gold and amalgam, in fact any metal, should be avoided for teeth which are of such soft structure that the pressure produced in inserting gold would tend to break down the tubuli, while metals never stand well in teeth of very soft structure. In fact, you can as well expect to prevent water flowing under the edge of a board resting on the ends of the blocks in cedar block pavement in the street, as to expect to exclude moisture from a soft tooth with a metallic filling, as moisture is bound to penetrate between the tubuli. Even the normal plasma exuding from the tubuli will have a tendency to assist the destruction of the hard structure when it becomes vitiated, as it must in the temperature of the mouth, as it is a foreign substance when lost from the tubuli, as is the blood that weeps from abraded gum tissue.

The cements and gutta percha are the only filling materials that should be employed for filling such teeth. If you will use these materials, in the course of eighteen months or two years the tooth will be found quite hard, and capable of proper manipulation, to prepare it for the king of metals and the king of filling materials—gold. A tooth treated in this way will not be as sensitive, and the fillings will last.

Dr. Williams: In this experiment one element is amalgam. What is the composition of that amalgam?

Dr. Whitefield: Ordinary commercial amalgam. I don't remember its composition.

Dr. Williams: One point that I can see in this paper is, that what we have practiced can be verified by strict scientific experiments. I will simply say one or two words that I have noticed from general observation, and am convinced that amalgam with zinc is more liable to produce galvanic action than without zinc. Another point is, that in several cases where there has been decided galvanic action, I have found that the galvanic action was less or not existing at all by combining as large a proportion of gold foil with the amalgam as possible. It is on the theory in a general way that by mixing the gold, if there is gold filling near, it lessens the difference between the metals and so lessens the galvanic action; that is my theory, practiced on for years.

Dr. Marshall: I am interested in this paper, and also in the experiments, and have this to say of some experiments I have seen. Dr. S. P. Palmer of Syracuse, N. Y., demonstrated fifteen years ago, or rather I should say proved very conclusively that there was not only action between teeth structure and metal fillings, gold and amalgam plugs, but also between gold and tin,

and between tin and amalgam, but of course the action was not so great between the latter as between gold and amalgam. He also went considerably further than this in his experiments. He proved conclusively that a galvanic action was established between any two dissimilar materials when moistened with a solution of chloride of sodium or saliva producing a distinct deflection of the needle. Another experiment seemed very strange at the time; for instance, he was in the habit of taking two foods which we eat in pairs, as the most palatable, such as ham and fried eggs, a piece of mutton and tomato sauce, a piece of turkey and cranberry sauce, in fact he followed it all through the foods which we naturally eat in pairs as being most palatable, and he found that by moistening these with saliva that there was a deflection of the needle as a result. He then made this suggestion, that it was on account of this peculiar galvanic or electrical action present between certain dissimilar bodies or kinds of foods, zest of taste or relish is given; that by the decomposition of the saliva produced by the electrical action between the foods.

"How many of us ever tasted water as good as that of the well on the old farm. Dr. Palmer would ask what did you drink out of, the tin dipper? The contact of the metal dipper with the moist lip produces a galvanic current. That is the solution of it." I am inclined to think that there is a good deal in this. I just mentioned this to show what has been done experimentally in this very direction by Dr. Palmer. Most of you know that Drs. Palmer, Flagg and Chase were the three men who made up the new departure trio. Their idea was that gold was not always the best material to use in the filling of teeth; that sometimes amalgam was better than gold itself; on account of the low galvanic condition which existed between amalgam and some of the baser metals and tooth structure.

Dr. Williams:—There is one point in regard to Dr. Palmer's idea that I would mention which I think is a little wanting, because I think as a general thing, and certainly the poet so mentions it, that the most delicious flavor of water is from an "old oaken bucket."

Dr. Marshall:—Another point Dr. Palmer in his experiments also proves was that just as soon as the surface of the amalgam plug became thoroughly oxidized the electric current ceased. It was only in such cases in which the plug remained bright that this action continued. You all have, no doubt, noticed that when an amalgam plug has been placed in a tooth in contact with a gold plug, in a few days oxidation commences; and it used to be thought that we must leave a bridge or partition of dentine or tooth-structure between the two plugs, but we found after a time that the tooth at the cervical margins of the plugs was very soon dissolved

away, and that when you allow them to come in contact this condition did not occur.

Dr. Custer:—I think you might gather from this that the amalgam which oxidizes most easily will be the best.

Dr. Whitefield:—I made a statement that where amalgams oxidize rapidly they are best; zinc will never oxidize thoroughly. I will state the following cases: a patient came to me for treatment and while under my care she complained that the fillings that had just been inserted were giving trouble. It immediately called my attention to the electrical action. I removed the amalgam filling and in a short time all trouble stopped. Using amalgam in preference to gold in some cases has been suggested. In some cases they need a kind of a whip. There needs to be some kind of a stimulant.

Dr. Williams:—I would like to say that I hope that Dr. Whitefield will try a suggestion of mine which is to mix as much gold as possible and then to put it under test. I hope he will try it practically, scientifically and mathematically; not try to find a certain thing, but try to see what he can find.

Dr. Marshall's paper was next read:

THE RHEUMATIC AND GOUTY DIATHESIS, AS MANIFESTED IN DISEASES OF THE PERIDONTAL MEMBRANE.

BY JOHN S. MARSHALL, M.D.,
OF CHICAGO, ILL.

In nearly all our text books on dental surgery and dental pathology, mention is made of the fact that rheumatic and gouty individuals sometimes suffer from irritation of the peridental membrane, causing the teeth to become more or less sore and loosened in their sockets; supposedly the results of the peculiar diathesis of the system, but farther than this no light is thrown upon the subject.

Clinical and post-mortem experience teaches that the *materies morbi* of these diseases has a predilection for the fibrous structures of the body, especially the synovial membranes, the aponeuroses of muscles, the dura mater, the cardiac tissues, periosteal and peridental membranes. The one most commonly affected is the synovial membrane, resulting in inflammatory conditions of the joints.

It not uncommonly happens, however, that there is associated with the inflammatory phenomena of the joints, enlargement of the long bones and nodular formations in other localities; and in the peri-cementum, conditions which are somewhat analogous.

The predisposing and exciting causes of certain irritative conditions of the peri-cementum seem to have their origin in the same conditions which bring about the phenomena of gout and

rheumatism, and they have also proved by experience to be amenable, in many cases, to the same specific treatment adopted in these diseases. This last fact has led me to the belief that the rheumatic poison is largely accountable for many of the diseased conditions of the peri-cementum, and has induced me for several years to make close and careful observation in relation to the prevalence of irritation of the peri-cementum in gouty and rheumatic individuals.

This belief has been further strengthened by finding upon analyzing the urine of a number of persons suffering from peridental irritation of this character, that there was a considerable excess of uric acid in every case. The saliva also, in many cases, gives a decided acid reaction.

The peridental membrane seems to be very susceptible to the irritating effects of an acid condition of the blood, whether from an excess of lactic or uric acids retained in the system or from the ingestion of such acids as are found in sour wines and malt liquors.

The habitual use of sour wines and malt liquors often results in peridental irritation of a marked character, in individuals who have never developed symptoms of a rheumatic condition; while on the other hand the same irritative conditions are found in total abstainers: but these, it would seem, are due to rheumatic phenomena and are often the forerunner of an approaching attack of acute articular inflammation.

Congestion and thickening of the peridental membrane and temporary loosening of the teeth, accompanied with dull, gnawing pains and more or less soreness are a common occurrence in rheumatism and gout. At times this condition is the first definite system to be manifested of an approaching attack of acute articular inflammation, while in others it does not make its appearance until after the first acute symptoms have subsided, and occasionally it is the only manifestation of this peculiar diathesis.

Chilling the surface of the body, or in other words taking cold, is usually the exciting cause of an attack, while an injudicious diet greatly aggravates it.

The presence of concretions upon the roots of the teeth is the most common cause of inflammation of the peri-cementum, and it has been generally supposed that these concretions were formed from the saliva.

It is my purpose to call attention to what seems to me to be a more rational explanation of the formation of these deposits in locations where the saliva could not, or could with great difficulty, reach. The saliva contains, as waste products, a certain amount of phosphate and carbonate of calcium which has been rendered soluble by the action of carbonic acid. A certain amount of ammonia is given off from the lungs as a product or decomposition of tissue; while

fermentation of alimentary débris lodged about the teeth also furnishes an additional amount of ammonia. This ammonia coming in contact with the saliva in the mouth, unites with a portion of the carbonic acid to form carbonate of ammonia, thus liberating a portion of the calcium which is thrown down in the form of a precipitate and lodges upon the exposed surface of the teeth. But when deposits occur at remote points from the gum margin, it does not seem possible that this is the correct explanation of their presence in these locations. The law of gravity carries all bodies that are heavier than the medium in which they are suspended, downwards; consequently we must look for some other explanation for the presence of the deposits on the roots of the superior teeth.

Capillary attraction may possibly account for their location, but this seems hardly probable, for it presupposes the presence of a pocket, or a separation of the peri-cementum from the cementum, while the amount of saliva entering such an existing *cul-de-sac*, would be extremely small, and not likely to be changed at sufficiently frequent intervals to account for the rapid accumulation which takes place in some of these cases. We are forced, therefore, to the supposition that they are deposited from some other source, and under an entirely different group of circumstances.

It has been suggested by Dr. Ingersoll of Keokuk, Iowa, that these concretions were a direct deposition from the *liquor-sanguinis* which bathes the roots of the teeth during the suppurative stage of the inflammatory process. This may be the correct solution. It is true that calcareous material is sometimes deposited from pus, in proof of which might be mentioned the fact that the roots of teeth penetrating the antrum of Highmore and foreign bodies located in this sinus during suppurative inflammation, have been found when removed to be covered with calcareous deposits, but that this is a common occurrence in suppurative conditions in any locality, admits of serious question. I am of the opinion, however, that the deposition of the concretions upon the roots of the teeth in those localities not readily reached by the saliva, or in which the presence of the saliva would be an impossibility, are due to the causes which produce the chalky formations found in the joints and fibrous tissues of gouty and rheumatic individuals.

The thought has occurred to me, though I have not had time to demonstrate it positively, that the concretions found upon the roots of the teeth in the locations just named were masses of urate of soda with phosphate and carbonate of calcium, and that they are deposited directly from the secretions, as is often the case in rheumatic arthritis.

Furthermore, it would seem that these concre-

tions were the cause of the inflammatory condition, rather than the result of it; in proof of this let me state that clinical observation teaches that suppuration often occurs about the roots of the teeth at remote points from the gum-margin, and which have no outlet until the peri-cementum is dissected from the roots of the teeth by the accumulation of the pus. I have seen cases in the lower jaw in which an abscess had been formed upon the roots of living teeth, between the neck and the apex, and in which the attachment of the gum at the neck of the tooth was intact and the pus did not escape until nature had perforated the soft tissue, or relief was given by the use of the knife. In such cases I have never failed to find concretions upon the root at the point of suppuration; this could not possibly have been deposited from the saliva, and it is fair to presume that the deposits upon the root was the source of irritation that produced the abscess, rather than that the inflammatory condition was produced by some remote cause and the formation of the deposit the result of the inflammation.

Dental exostosis, or hypertrophy of cement tissue, is an occasional occurrence in individuals of a gouty or rheumatic diathesis. It is most commonly found in chronic cases of long standing, and is often associated with enlargement of the joints.

The causes are in all probability the same as those which produce the enlarged joints. Chronic irritation of the periosteum tends to hypertrophy of bone; while the same condition of irritation in the peri-cementum produced hypertrophy of the cementum. The history of these cases is usually one of chronic irritability of the peri-cementum with periodical attacks of soreness and looseness of the teeth, while the cause of each attack is generally referred to some recent exposure in which the individual has taken cold. The acid reaction of the saliva and the urine at these times gives evidence of an acid condition of the blood. This would seem to indicate the cause of the irritation and suggest the line of treatment to control the immediate symptoms and the prophylaxis of the future.

Phagedenic Pericementitis is sometimes directly traceable to a rheumatic condition of the system or the uric acid diathesis. In several cases in which I have analyzed the urine, uric acid was found largely in excess of the normal quantity.

In all of the cases which I class as rheumatic, concretions are found upon the roots of the teeth, and many times in locations which preclude the possibility of a salivary origin.

Under restricted diet in which meats, wine and malt liquors are cut off, there is soon a marked diminution of the quantity of uric acid excreted, and an equally marked improvement takes place in the symptoms manifested in the

oral cavity, which cannot be accounted for by the removal of the concretions and local treatment alone. In one case which has been under observation for four years, the periodical aggravation of the oral symptoms are a sure indication of the presence of an excessive amount of uric acid in the urine, and as soon as this condition is corrected the inflammatory conditions of the peri cementum are greatly relieved. Local treatment is necessary, but this alone is not sufficient; we must strike deeper and correct the morbid condition of the system if we hope to effect a cure.

Other cases might be cited that would seem to further substantiate the opinions already expressed, but time will not permit. I trust, however, the matter has been so presented as to stimulate farther investigation into this subject, and I believe if your observations are carefully made you will agree with me that the facts and opinions presented warrant the supposition that gout and rheumatism are important factors in the production of a considerable variety of irritative conditions of the peridental membrane.

7 Jackson Street, Chicago.

(To be concluded.)

BOOK REVIEWS.

MINOR SURGERY AND BANDAGING, including the treatment of Fractures and Dislocations, etc. By HENRY R. WHARTON, M.D. Philadelphia: Lea Bros. & Co., 1891. Chicago: A. C. McClurg & Co. Svo, half calf, pp. 497. Price \$3.00.

The introduction of a new plan of bandaging in accordance with the teachings of antiseptic surgery has rendered many of the books on bandaging obsolete, and the present book fairly supplies the defect. It is a pleasure also to note that the writer is an American, familiar with American surgical appliances, which have too frequently been ignored in the foreign reprints with which the market has hitherto been flooded. Notwithstanding this we notice many familiar illustrations from the text books that flourished many decades ago.

In the main, the work is fairly illustrative of current minor surgery, but we suggest that in the next edition a more recent method of skin grafting be described than the old one on page 185. There are many cases in which the old Hamilton-Reverdin plan may be supplanted by the Thiersch method with advantage to the patient.

PRACTICAL INTESTINAL SURGERY. By FRED B. ROBINSON, B. S. M.D. Vol. ii, paper, pp. 206. Detroit: Geo. S. Davis, 1891. Price 25 cents.

The concluding volume of Robinson's Intestinal Surgery is a great improvement over the first volume; more care has been exercised in the proof reading, and the unfortunate lapses that we were obliged to mention, do not disfigure the volume under consideration. This volume shows careful experiments concisely set forth, with logical deductions therefrom.

There are eleven chapters, which comprise the main portion of the operative surgery of the work. Gastro-enterostomy, Gastrostomy and Resection of Intestine are here treated, and some interesting experiments on gunshot wounds of abdomen are given. At the end of the book a number of diagrams appear, illustrative of the various forms of mechanical "aids" to intestinal surgery, and the different forms of suture.

In concluding the notice of the book as a whole, we have to say that the excellence of the second volume causes us to overlook the faults of the first, and to commend the volumes as a valuable contribution to the literature of the subject.

THE MICROÖRGANISMS OF THE HUMAN MOUTH. The Local and General Diseases which are caused by them. By WILLOUGHBY D. MILLER, D.D.S., M.D. Professor at the University of Berlin. With one hundred and twenty-eight illustrations, one chromo-lithographic and two photo-micrographic plates. Philadelphia: The S. S. White Dental Mfg. Co. 1890.

The opening chapters of this volume are occupied with studies of the morphology and biology of bacteria, their vital manifestations and the methods of conducting bacteriological investigations. The procedures in the culture of bacteria are well described and illustrated. The body of the work is given to the consideration of the rôle which pathogenic bacteria plays in the production of diseases of the mouth and teeth. The chapters upon their agency in the production of dental decay are of special interest, and as such are a valuable contribution to the literature of dental pathology. While the volume is one specially designed for those who make the study of diseases of the mouth and teeth a specialty, it may well command the attention of the general practitioner, as it very properly considers the agency of microbes developed in the mouth, in the production of various diseases of the respiratory and digestive organs. The work gives evidence of much original and valuable research and will well repay a careful study.

A PRACTICAL TREATISE ON DISEASES OF THE SKIN. By HENRY G. PIFFARD, A.M., M.D., Clinical Professor of Dermatology, University of the city of New York, etc., assisted by ROBERT M. FULLER, M.D., with fifty full page original plates and thirty-three illustrations of the text. New York: D. Appleton & Co. 1891.

The plates of this work are a distinguishing characteristic. The avoidance of the misleading effect of the ordinary chromo-lithographic illustrations is to be commended. The plates were prepared from photographs, many of which were taken by the author himself, with artificial light which he says he prefers to ordinary daylight. The result is much more than the ordinary one in the effort to represent the appearance of pathological changes in the skin, and approaches more nearly the effect secured in wax preparations in demonstrating skin disease. The method has the advantage over such preparations of affording an exact photographic illustration of a case in clinical practice, which is always more satisfactory, if well executed, because of its being known to have existed, than any preparation however skilfully executed.

The text is concise—the descriptions are good, and the work will be recognized as entirely modern. The paper and presswork are superior in character, and the book is well bound.

The effect of the combined work is such as to make the physician desire to possess it.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the Treasurer, Richard J. Duglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Duglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, OCTOBER 17, 1891.

PEDIATRICS.

A correspondent writes: "In one of your recent issues is found the announcement of the 'Third Annual Meeting of the American Pediatric Society.' Permit me to ask if it does not smack of affectation to give a name to a *National* Medical Association, which cannot be found either in DUNGLISON'S Medical Dictionary, or that of WORCESTER or WEBSTER, except, perhaps, in the most recent edition of the latter, which is in the possession of comparatively few persons. Will you kindly enlighten some even of your readers by giving definition of the word *pediatric*, and much oblige one of the latter."

The word *pædiatrics*, or *pediatrics*, as it is more frequently spelled to-day, is from the Greek, *παῖς, παιδός*, a boy, or child, and means diseases of children, or rather, the biology of childhood. Even the last edition of WEBSTER does not give this word, which is the more surprising, as it has been in somewhat extensive use for several years. Our correspondent should remember that dictionaries do not lead, but follow. We are unable to say how long the word has been in use, but certainly long enough to have found a place in first-class dictionaries.

We are inclined to think, however, that our correspondent's objection is not to the word *pediatrics*, but is intended as a criticism of the pur-

poses of the society which devotes its efforts to the special study of the diseases of children.

Such great advances in the elucidation of the diseases of children have been made in recent years that it is worth while to see in what way it claims to be a specialty in medicine, and upon what grounds these claims rest.

The first systematic treatise upon the diseases of children appeared in Stockholm in 1753, the work of ROSEN V. ROSENSTEIN. This work¹ went through several editions, and was translated into German, Dutch, English, French and Italian. Later came the works of HARRIS, ARMSTRONG and UNDERWOOD in England, and still later that of BILLARD in France. These works did very little more than collate the ideas then extant on the diseases of children and form groundwork for the advancement of the subject. Nevertheless, even ROSENSTEIN expresses dissent from the prevailing idea of the etiological importance of "teething," and states that most often the troubles attributed to it will be found due to other causes. It was too much to expect that he could entirely emancipate himself from this fetich, and so we find him giving directions for determining when the teeth are at fault. Worms, however, held full sway, and the longest chapter in his book is on this subject. Sixty years ago BILLARD quoted GUERSANT on the etiological influence of teething, and agreed with him completely as to its insignificance.

Like "cold" later in life, "teething" since the days of HIPPOCRATES, has been credited with causation of most of the diseases of infancy, and like "cold," "teething" is being gradually pushed into the background. At the close of the Newport meeting of the Association, the chairman of the section of Diseases of Children remarked that he was delighted to say that never once during the session had he heard of "teething" or "worms." The ignorance which has ascribed such importance to "teething" and "worms," has assisted materially in maintaining the mortality rate of infancy. Better diagnosis with correspondingly better treatment, is taking the place of "teething" and "worms." It may be truthfully said, that the number of cases of "teething" and "worms" occurring in the practice of a given physician is an exact index of his inability to

¹ Underrättelse om Barns Sjukdomar och deras Bete-Medel. (Observations on the Diseases of Children, and Their Treatment.)

diagnosicate the diseases of infancy and childhood.

We have mentioned these older writers merely to show that the special study of pediatrics is by no means new. To even hint at the later literature of this branch of medicine cannot be done with the space at our disposal, but it seems impossible to avoid mentioning the works of EVANSON and MAUNSELL, RILLIET and BARTHEZ, in France; HENOC, GERHARDT, STEINER, and VOGEL in Germany; WEST in England; EBERLE, and MEIGS in America. The literature of the diseases of children has increased immensely in recent years. Systematic treatises, and monographs on special subjects abound. No less than five periodicals, three in Germany, one in France and one in the United States, devoted to this special subject, bear evidence of the increasing attention paid to pediatrics. Its crowning literary jewel has appeared in America, in KEATING'S *Cyclopædia of the Diseases of Children*, a monument to the industry of its writers, and an earnest of the work which has already been done, and of the importance of the subject. If children were little men and women there would not be a specialty of pediatrics. But they are not. They have their anatomical and physiological peculiarities, their own hygiene, their own pathology, their own diseases, their own therapeutics. Special methods of diagnosis are necessary in infancy, and the physiognomy of disease here is peculiar. Prognosis does not follow the same lines as in the adult. The great problems of nutrition here find their peculiar field, and upon their proper solution depends the welfare of the future man or woman. These grounds seem sufficient to entitle pediatrics to the position of a specialty in medicine. As a few examples illustrating these statements might be mentioned the anatomical peculiarities of the naso pharynx in the infant, particularly the small size of this space. This diminution in size makes coryza, so insignificant in the adult, often a matter of great importance to the infant, not infrequently leading indirectly to serious disturbance of nutrition. Enlargement of the bronchial glands is particularly a disease of childhood. Empyema is much commoner in children than in adults, and more insidious in its onset, frequently existing for months before detection. Rickets and allied forms of malnutrition are often overlooked in the

child until their greatest damage has been done. Many of the neuroses of malnutrition in the infant are not recognized as such. The diseases of the mouth are most frequently met in childhood, and have quite a different significance from the same diseases in the adult. The great group of diseases of the alimentary canal differ so widely from similar diseases in the adult, that their successful handling must be conducted on an entirely different basis from their treatment in adult life. The single subject of infant feeding, particularly artificial feeding, is so beset with difficulties that one might almost say that it alone is worthy of being raised to the dignity of a specialty.

Pediatrics certainly is not a specialty in the sense ordinarily employed, which gives this title to the special study of the diseases of a single organ or system. And yet like these branches of medicine, it requires special training on the part of its practitioners, and has been most advanced by those who have given their time and study to it as a specialty. It is in one sense the least narrowing of all specialties because its workers must keep always before them the future man. "The child is father to the man," was the title of the address of the President of the Children's Section, of the British Medical Association at its last meeting, and while he strove hard to deny that pediatrics is a specialty, his address belied his words, as he showed most conclusively that the proper handling of the child had much to do with the success with which the future adult should avoid or bear the diseases to which he might be exposed.

Pediatrics is the specialty which the general practitioner most needs, and yet it is painfully apparent to all that the teaching of this subject is sadly neglected in most medical schools. In but very few schools is that systematic instruction given, which is essential to the full appreciation of the subject, and even clinical instruction in this branch is often relegated to a secondary position.

NEW MUNICIPAL HOSPITAL, BOSTON.—A new cottage hospital has been planned, for the treatment of women, in Boston Harbor. It will be located on property belonging to the city on Long Island. The first ward building that will be built will be 140 feet long, with a capacity of 100 beds. The amount of the appropriation is \$50,000, with an increase expected in future years.

THE LEPER-PRIEST OF SURINAM.

The editor of the *British Medical Journal*, once in commenting on the life work of Father DAMIEN of Molokai, quoted that sentiment of EMERSON, which declares that "Nothing truly great was ever achieved without enthusiasm." The same sentiment is equally applicable to another, but comparatively unknown priest who has recently died in the service of a colony of forlorn lepers. Father JOHN BAKKER was truly a hero of the type of DAMIEN, and like him contracted leprosy and died of it in consequence of his labors. Father BAKKER'S field was near Batavia, in Dutch Guinea or Surinam. He was a Redemptorist priest, a native of Amsterdam, Holland, about fifty-eight years of age. During the greater part of the last twenty years his life has been devoted to the care of lepers. The first signs of his malady appeared nine years ago, while he was living at a plantation called Livorno, a short distance from Paramaribo, the capital of the province. For the past six years he has resided in the Batavia leper-colony, with the expectation that he would die there with only his fellow lepers around him. It is reported that he suffered greatly towards the last of his sickness, being confined to one small room, and yet maintained a cheerful and heroic aspect through it all.

Concerning the field in which his best years were spent, it is said that there are not less than three thousand lepers in the country. Many of these reside at the capital city, staying in their houses during the day time, but greatly given to wandering about at night, regardless of law or sanitary precaution, and not at all amenable to discipline. The Governor, a man of enlightened views, has done much to check the spread of the disease, and is about to establish a hospital for the systematic treatment of suitable cases.

The points of parallelism between the two leper-priests, whose names appear above, and their lives of voluntarily exile, are sufficiently numerous to create in us no little surprise that so obscure has been the fame of one, while the other has engaged the attention of princes and rulers, and his fate has been narrated again and again in all its mournful but romantic details. If we mistake not, Father BAKKER preceded Father DAMIEN in his departure from Europe, and is in point of fact the true pioneer in this

line of desperate missions. And, further, it would appear that he was the first one of the two who became affected with leprosy. But honor to them both—*par nobile fratrum*—they were doubtless unconscious rivals in heroism.

BLOOD-LETTING IN URÆMIC CONVULSIONS.

DR. SAMUEL WILKS, veteran physician at Guy's hospital, is reminiscent, in a recent *Lancet*, of the good old days of blood-letting. He remembers seeing too many interesting persons snatched by this agency from the brink of the grave, to be unmindful of its claims, and he attempts to find excuses for the present day and generation in its neglect of phlebotomy. Of his success with the lancet he writes the following:

"A young woman was brought into the hospital in a dying state, gasping for breath, and livid; there was a mitral bruit, engorgement of the lung with hæmoptysis, albuminous scanty urine, and dropsy. We bled her from the arm and the effect was immediate, the breathing became tranquil, lividity passed from the face, and improvement continued from that time. In cases of *uræmic convulsions* the effects of bleeding are very striking; the right heart is relieved, and poisoned blood is removed from the system. One case of this kind, indelibly fixed in my memory, is that of a dressmaker, who, I believe, is still alive. I was asked a few years ago to see this patient, who had been in convulsions all night. I found a middle-aged woman in constant convulsive movements, froth issuing from her mouth, quite comatose, and almost pulseless. The whole body was livid and the extremities cold. The doctor said she was dying, and allowed me therefore to bleed her. I took away a small wash hand basin of blood, and while yet flowing, the lividity passed off, the convulsions ceased, the body gradually became warmer. Her life was as clearly saved by the bleeding as if I had dragged her drowning out of the water, and this is more than I can say of drugs." With this, are other instances of the same tenor.

A UNION MEETING OF THE DISTRICT MEDICAL SOCIETIES OF NORTHERN OHIO.—A union meeting of the Northwestern the Northern, and the North Central Ohio Medical Societies will be held at Mansfield on Thursday, Friday and Saturday, November 5th, 6th and 7th.

SOCIETY PROCEEDINGS.

American Orthopedic Association.

*Fifth Annual Session, held at Washington, D. C.,
Sept. 22, 23, 24 and 25, 1891.*

ORTHOPEDIC SURGERY AS A SPECIALTY.

DR. A. B. JUDSON, of New York, in the President's address, said that orthopedic surgery is specially the domain of physical demonstration, where subjective symptoms give place to objective signs, where treatment is chiefly mechanical, and where results are recorded in degrees of a circle and fractions of an inch. It exists and thrives as a specialty, because the general practitioner concurs with the public in committing patients who, from the nature of the case, generally recover with some deformity and disability, to the care of experts.

DR. N. M. SHAFER, of New York, defined orthopedic surgery as that department of surgery which includes the prevention, the mechanical treatment and the operative treatment of chronic or progressive deformities, for the proper treatment of which special forms of apparatus or special mechanical dressings are necessary.

DR. V. P. GIBNEY, of New York, proposed a definition as follows: That department of general surgery which includes the prevention, the mechanical treatment and the operative treatment of chronic or progressive deformities.

ORTHOPEDIC NOSOLOGY.

DR. W. R. TOWNSEND, of New York, advised the construction of a uniform nomenclature for orthopedic affections, to facilitate the taking of histories, and to increase the value of reported cases. A committee was appointed for this purpose.

THE LATE MR. THOMAS.

DR. A. J. STEELE, of St. Louis, paid a friendly tribute to the late Mr. Thomas, of Liverpool, a Corresponding Member of the Association, whose methods have been so widely discussed, and whose influence is felt in many branches of orthopedic practice.

CRURAL ASYMMETRY AND LATERAL CURVATURE.

DR. H. L. TAYLOR, of New York, described two cases in which the leg was two inches, and one and one-eighth inches short respectively. Both cases were in young women. The short limb was larger and stronger, the shortening was chiefly below the knee, and there was no lateral curvature.

DR. A. HOFFA, of Wurzburg, Germany, described a specimen which proved that in one instance the shortness was due to union of the neck and shaft of the femur at an acute instead of an oblique angle.

DR. F. BEELY, of Berlin, illustrated with specimens of lateral curvature and ingenious models, the changes which occur in the bodies of the vertebrae preceding rotation, explaining how the paraspinous sulcus is shallow and broad on the concave, and deep and narrow on the convex sides, a condition which is reversed in the lumbar region by the absence of ribs.

SPINA BIFIDA AND CLUB FEET.

DR. H. A. WILSON, of Philadelphia, related the case of a child of four years. The ordinary methods of reducing the deformity of the feet excited suppuration, which resisted treatment for six months, as long as the patient remained under observation. There were sensory paralysis and deficient circulation in the lower extremities. The same intolerance of surgical treatment thwarted all attempts to treat the spinal tumor.

DR. L. A. WEIGEL, of Rochester, had had similar trouble with a similar case, but found that when the child was older, it was possible to treat the deformity of the feet with success.

DR. A. E. HOADLEY, of Chicago, related a case of spina bifida, in which good result had followed an operation in which he did not attempt to repair the vertebral deficiency, but had simply turned up large flaps, and united them by silk sutures.

DR. T. M. L. CHRYSTIE, of New York, reported a case of congenital equino-varus, with absence of great toe and contiguous bones of the instep. Mechanical treatment speedily reduced the deformity, with a gain of symmetrical gait.

DR. W. E. WIRT, of Cleveland, related an interesting and unusual case of club-hand and club-foot, with other congenital malformations.

DR. HOFFA said it was evident that all cases of club-foot do not have the same causation. The cases reported were due to some fault in the earliest stages of development.

SPASTIC PARALYSIS AND SPINA BIFIDA.

DR. W. N. BULLARD, of Boston, reported a successful operation by Dr. C. L. Scudder, of Boston, for the relief of spastic paraplegia in a child with spina bifida. He thought the paraplegia not due directly to the spina bifida, but to the accompanying hydrocephalus. He advocated electrical treatment, and faradization rather than galvanism.

DR. WEIGEL reported a case in which division of all shortened tissues, and the use of a brace, had secured a favorable result.

DEFORMITY AFTER KNEE-JOINT EXCISION.

DR. J. C. SCHAPPS, of Brooklyn, said that after excision, the two united epiphyses make a mass of soft bone, in each end of which is inserted a long lever. With this leverage, it is possible to restore and maintain a straight limb by simple mechanical treatment.

DR. A. M. PHELPS, of New York, thought that recurrence of deformity can be prevented by liberal resection of the hamstrings.

DR. HOFFA said that relapse often occurs from incomplete removal of diseased tissue, and that when excision is done in early life, and all disease removed, marked shortening will not occur.

DR. BEELY said that flexion could be prevented by over-correction, but at the risk of further over-correction as the result of locomotion. Apparatus designed to prevent recurrence of deformity should relieve the limb from the weight of the body.

DR. TAYLOR objected to free division of the hamstrings, as these muscles are useful in balancing the pelvis on the femur, even after motion at the knee is abolished.

DR. J. D. GRIFFITH, of Kansas City, had prevented flexion by removing all the disease, and without dividing the hamstrings.

DR. SCHAPPS said that in many patients under 10 years, excision was to be preferred to mechanical treatment.

KNEE TROUBLES IN LOCOMOTION.

DR. SHAFFER related a number of cases in which an elongated patellar ligament had caused pain and difficulty in locomotion.

DR. AP M. VANCE, of Louisville, thought that the ligament might become shorter if not constantly stretched by use. Rest was indicated.

DR. GIBNEY cited a case in which rest for one and a half years had not caused shortening.

DR. SHAFFER said his patients had been benefited by giving lateral support, thus converting the joint into a true hinge.

ATROPHY IN JOINT-DISEASE.

DR. E. G. BRACKETT, of Boston, argued that atrophy is due to disease, and not entirely to reflex irritation.

DR. A. G. COOK, of Hartford, said that atrophy of the foot, often very marked, can be only the atrophy of disuse.

DR. J. K. YOUNG, of Philadelphia, believed that the atrophy in question is the result of reflex interference with nutrition. In hip disease, it appears first in the thigh muscles, especially the adductors.

ATROPHIC ELONGATION.

DR. ROSWELL PARK, of Buffalo, described the atrophic elongation conspicuous in the lower extremity. As the result of disuse from disease, with avoidance of pressure on the bone ends, the bone lengthens more rapidly than its fellow. This is illustrated in growing children with disease of the tibia or femur, and is noticeable in some cases of hip disease.

TREATMENT OF HIP DISEASE.

DR. PHELPS said that traction and fixation

should be enforced, to prevent destruction by intra-articular pressure. Ankylosis is the result, not of fixation, but of disease. The patient should be put to bed from three weeks to four months, and should then wear the lateral traction fixation splint which was exhibited. Children under 3 years are placed in the plaster of Paris portable bed, which was also shown.

DR. WIRT exhibited a new device for traction, in which the force of the lever is changed into rectilinear instead of circular motion, without key, screw-driver, wrench, buckle or strap.

DR. R. H. SAYRE, of New York, said the invention gave accurate and easy adjustment in the direction of traction, but in the direction of relaxation, the control was defective.

DR. A. J. GILLETTE, of St. Paul, was satisfied with the results obtained by the use of Thomas' splint.

DR. VANCE said he practiced fixation at the hip, but believed much depended on the surroundings of the patient.

DR. SHAFFER believed the best results can be obtained by the use of the long Taylor traction splint. He thought results should not be reported till six years had passed, as relapses were not uncommon.

DR. RIDLON, of New York, said a splint should secure immobilization by antero-posterior leverage, as in Thomas' splint, by an action identical with that of the Taylor spinal brace.

DR. STEELE approved of the combination of the English method of rest with the American plan of traction.

DR. TAYLOR practiced rest in bed with traction in the acute stage, to be followed by a splint which allows locomotion.

DR. SAYRE thought but few cases required lateral traction. When the inflammation had ceased he applied passive motion. If the pain and tenderness following last more than twenty-four hours the passive motion had not been rightly used.

DR. E. M. MOORE, of Rochester, believed that a joint only *moderately* inflamed, demands motion. He employed traction with a certain amount of motion.

CONGENITAL DISLOCATION OF THE HIP.

DR. PHELPS exhibited apparatus for the treatment of this affection, and described his method, and its results.

DR. E. H. BRADFORD, of Boston, had modified the apparatus in previous use by adding an appliance with which the patient is allowed to walk about. The joint is thus protected as in convalescence from hip disease. These appliances he had made of aluminum for the sake of lightness.

DR. C. C. FOSTER, of Cambridge, said the best recorded result had been obtained by Dr.

Buckminster Brown, whose patient was treated by mechanical means in bed.

DR. A. HOFFA had operated by deepening the acetabulum, which is practicable from the thickness of the pelvis at this point. At first, he sewed a periosteal flap over the trochanter, but this is unnecessary. Two months ago he examined his first case, two years after the operation, and found a movable joint, freedom from the characteristic gait, and absence of lordosis.

MR. HOWARD MARSH, of London, divided these cases into (1) those in which the bone slips about on the wall of the pelvis and (2) those in which it is fixed. The majority belong to the second class and in these operation is useless, but is more properly applicable to those cases of the first class in which the head is high up and movable. The anterior position is the most favorable, because lordosis, which depends on the backward displacement of the head of the femur, is absent.

DR. RIDLON said that, as subjects for treatment, anterior dislocations are more hopeless than posterior ones.

DR. DE F. WILLARD, of Philadelphia, said treatment should be by forcible attempts at reduction, to excite inflammation, followed by traction and systematic exercise.

MALIGNANT DISEASE AND POTT'S DISEASE.

DR. JUDSON reported three cases in which Pott's disease and malignant disease of the vertebræ had been confounded by himself and other observers. In one the diagnosis was made ante-mortem. The patients were four-and-a-half, thirty-five, and forty-two years respectively. The chief diagnostic points are (1) deformity present in Pott's disease, absent in malignant disease; (2) local disability; and (3) local pain, both absent in Pott's, and present in malignant disease.

DR. WILLARD had seen two cases in which his diagnosis was confirmed post-mortem.

DR. GIBNEY reported a case in a man of forty years, in which he and others had been baffled in diagnosis. There was sarcoma of the fifth and sixth cervical vertebræ.

MR. MARSH related the case of a child which was extremely difficult to diagnosticate, and which proved to be malignant in character.

SYPHILITIC POTT'S DISEASE.

DR. RIDLON said that in this form, the onset is more rapid, the pain and disability greater, the kyphosis sharper in outline, and abscesses often appear before deformity. If recognized lesions of hereditary or tertiary taint are present, treatment should be by large doses of mercury and iodide of potassium.

DR. B. LEE, of Philadelphia, referred to cases of this origin, which had come under his observation.

POTT'S DISEASE IN THE OLD.

MR. MARSH had observed instances of suppurative tuberculosis in the metacarpus, tarsus, testis, cervical glands, knee and hip in eight patients between sixty-three and seventy-three years. But senile tuberculosis of the spine is most rare. He had seen two cases. The patients were sixty-four and sixty-five years respectively. The College of Surgeons of London possessed an osseous specimen of the action of senile tuberculosis of the upper cervical vertebræ. In his "Studies of Old Case Books," Sir James Paget had recorded a case of Pott's disease in a gentleman of fifty-five, attended with angular curvature.

DR. SAYRE recalled the case of a patient, æt. 55, who recovered from Pott's disease with paraplegia and abscesses.

POTT'S DISEASE AND PREGNANCY.

DR. T. H. MYERS, of New York, had collected twenty-five cases of labor in fifteen patients recovered from Pott's disease. In no instance, did caries recur. But of seven cases in which the disease developed during pregnancy, three died, and three were left paraplegic. Normal parturition often follows in cases of deformed pelvis whose measurement would indicate that it was impossible. These patients should be examined by the obstetrician early in gestation.

DR. TAYLOR knew of many cured patients whose marriage had been followed by the birth of healthy children.

DR. G. W. RYAN, of Cincinnati, thought it was a question of allowing the tuberculous to marry. He knew of married women, deformed by Pott's disease, who had borne and raised healthy children.

DR. STEELE said one of his patients recovered from Pott's disease had borne six healthy children.

DR. LEE said one of his patients with a large lumbar kyphosis, had borne twelve children who, with the mother, are all in good health. He thought Pott's disease, even in the lumbar region, rarely produced narrowing of the pelvis.

DR. VANCE had seen a number of cases in which this deformity had not made labor of more than average difficulty.

PARAPLEGIA IN POTT'S DISEASE.

DR. BRACKETT said that relief from paraplegia may be confidently expected from continuous extension and fixation, even in cases of eighteen months' standing. This should be continued for some time after recovery.

DR. YOUNG reported two cases of complete recovery, in which there had been absence of sensation, a feature always of grave import.

DR. SHAFFER referred to a case in which the autopsy showed that a portion of the eighth dor-

sal vertebra had nearly cut through the cord, leaving but a slender thread.

DR. HOFFA said that in these cases, the spine should be put absolutely at rest. He had collected thirteen operations within the vertebral canal. Two died at once, two recovered, and would perhaps have done so any way. In the others, there were immediate good results but relapse soon occurred. The operation has no great future before it, and should be limited to those cases in which the processes alone are affected.

DR. S. KETCH, of New York, had now under treatment a patient who had been paraplegic for five years, but he still maintained a hope of effecting a recovery.

DR. HOFFA suggested that an abscess may be exerting pressure on the cord.

DR. MARSH said paralysis rarely depends on the pressure of an abscess; but, 1, on softening of the cord, 2, pressure of a displaced sequestrum, and 3, most common, on pressure from exudation. He would only operate after thorough trial of rest.

DR. WILLARD said we could not absolutely diagnosticate the cause. When there are extensive inflammatory deposits about the arches, laminectomy may relieve the posterior pressure and allow expansion of the cord.

DR. LEE said that in all cases of this form of paraplegia, suspension would materially hasten recovery.

ABSCESSSES IN POTT'S DISEASE.

DR. TOWNSEND thought that, as a rule, these abscesses should not be opened. In some cases, aspiration should be done, and in others, the cavity should be opened and drained to prevent sepsis and danger to life. His views were based on the history of 380 patients, 75 of whom had abscesses.

DR. YOUNG suggested the division of lumbar abscesses into external and internal, according to their relation to the psoas fascia.

DR. VANCE advocated aspiration, repeated as often as fluid is detected. In this way he cures three out of five cases. The depot is thus kept small and the extent of subsequent operations, if necessary, is limited.

MR. MARSH had rarely obtained a good result by the use of the aspirator.

DR. RYAN said he had found aspiration to be a poor dependence. When interference becomes necessary, he believed incision to be the most conservative and effective procedure.

MR. MARSH said that, in his observation, it is best to open freely, evacuate thoroughly, and then apply pressure to assist in closing the cavity.

B. E. HADRA, of Galveston, said that on general surgical principles such abscesses should be evacuated.

DR. WILLARD would let dormant and caseating foci alone, liquifacting collections; he would aspirate and inject with iodoform emulsion, and if true pus were present he would incise, wash out with sublimate solution, and avoid undue manipulation, which might cause fissures which would let the tuberculous poison into the system. He would then suture the incision, and inject iodoform and boiled olive oil.

DR. BRADFORD said that, while he did not think the danger from opening large abscesses was so great as had been thought by some, he was aware that absorption of such abscesses is not at all uncommon.

DR. J. E. MOORE, of Minneapolis, said the evacuation of a spinal abscess is a matter of great surgical responsibility, as it is an aseptic cavity, difficult to protect from infection after operation.

DR. HOFFA would open only those abscesses which cause severe pain, or are likely to give rise to septicæmia.

DR. LEE would never open an abscess of this kind unless compelled to by the conditions mentioned by the last speaker.

DR. KETCH said there was danger that in our anxiety to treat a secondary feature we neglect the disease itself.

DR. SHAFFER would not say that incision was never advisable, but generally it is wrong to open one of these abscesses. A very large abscess cannot be washed out, and its disappearance may be confidently expected, especially if efficient mechanical treatment is practicable.

DR. MYERS said that it was proven, 1, that it was impossible to completely remove bacilli from the abscess cavity, and 2, that bacilli-infected wounds at times, heal primarily. Infection is more imminent after incision, because the wound lays open channels of absorption.

WIRING THE VERTEBRAL PROCESSES.

DR. HADRA suggested that the spinous processes at the seat of the disease be exposed and then firmly wired together to secure rest, and prevent deformity. The operation, as he had performed it for fracture of the cervical spine, was extremely simple and effective.

DR. SAYRE thought the wires would not bear enough force to remove the weight from the vertebral bodies, and that outside protection would be necessary to prevent lateral and rotatory disturbance.

DR. JUDSON thought it was a question whether wiring was applicable through the long periods in which consolidation is delayed. Intolerance of the skin always prevents such pressure as we would like to make on the kyphos. The method proposed, circumvents this difficulty.

DR. R. WHITMAN, of New York, said that due consideration should be given to the difference

in development between the growing and adult spine.

DR. KETCH did not see how the proposed operation could take the place of apparatus.

DR. MOORE said it was a most simple and harmless procedure and notwithstanding the theoretical objections, he would accept the first favorable occasion to try it.

PROGNOSIS AND TREATMENT OF POTT'S DISEASE.

DR. KETCH had learned from 75 cured cases, that in length of treatment and degree of deformity, the upper region of the spine is most favorable, and the middle least of all, that paraplegia more frequently accompanies disease in the upper than in the lower regions, and that cases of traumatic origin, recover sooner than those of tubercular origin. Sudden deaths sometimes occur in cervical caries from interference with respiration.

DR. B. BARTOW, of Buffalo, said that the earliest important sign in the dorsal and lumbar regions is lateral curvature, dependent on nervous tenderness. Apparatus should be constructed to oppose the rotation accompanying the lateral curvature, as well as the antero-posterior deformity. He used the plaster of Paris jacket applied to effect the above objects.

DR. FOSTER said that extension in bed is the best method in the acute stage. Extension should be made by light weights, the cords leading over the head and foot of the bed and attached to waist-belts, chest-belts, and head-straps.

DR. WEIGEL reported a case of cervical Pott's disease, with abscess and paraplegia, successfully treated by extension in bed.

DR. RIDLON had kept patients in bed from three to four years, and had never seen a case which was not benefited generally and locally.

DR. RYAN said recumbency was the ideal treatment, but it is in many cases impracticable. He had found split plaster jackets efficient after the acute stage.

DR. LEE said that many years ago, when the plan had fallen into entire disuse, he was the first to adopt suspension from the practice of Dr. J. K. Mitchell. The apparatus was Le Vacher's head support and jury-mast, attached to a chair or go-cart, or to a doorway swing.

DR. SAYRE said that in the cervical and upper dorsal region, a metal posterior splint, supported on the pelvis, should be used with the jury-mast, and in the lower dorsal and lumbar regions, a plaster of Paris jacket with a jury-mast. Recumbency should be practiced in the acute stage; children should be placed in the wire cuirass.

DR. KETCH had been disappointed with the plaster of Paris and jury-mast in the cervical and upper dorsal region. He commended the Taylor apparatus and chin-piece. In the lumbar region almost any supporting apparatus will secure a good result.

DR. TAYLOR said that the antero-posterior lever secures rest and protection, and combats deformity. Old and neglected cases are especially amenable to treatment, as ankylosis is later and rarer than is generally supposed. Abscesses and paraplegia do not forbid a favorable prognosis.

DR. BRADFORD said that the plaster of Paris jacket was the readiest method, but had its disadvantages, that a steel brace gave better support, but demanded more skill and care, and that recumbency was the surest way to prevent deformity, but, as a rule, was impracticable for the long periods covered by the disease.

TYPHOID SPINE.

DR. GIBNEY reported an additional case of typhoid spine, in a man of 45 years, in which, different from the cases previously reported, there was marked deformity in the cervical region, dating back to typhoid fever at the age of 22. Two years of pain and disability had immediately succeeded the typhoid attack. Usually, the symptoms had not appeared till one or two months after the fever.

DR. HADRA recalled an epidemic of typhoid with so much tenderness on pressure of the vertebræ, that the affection was at first thought to be meningitis.

RHEUMATIC SPONDYLITIS.

DR. RYAN said that this rare affection should not be confounded with rheumatoid arthritis of the spine. It is usually accompanied by rheumatic manifestations elsewhere. In the early stage, the symptoms resemble those of tubercular spondylitis. Later, the deformity is not angular, but resembles that of senile kyphosis. Treatment should be directed to the relief of pain by support, cautery and medication. In the chronic form, when pain has lessened, mobility should be encouraged by passive motion.

DR. HOADLEY deplored the confusion which is found in the nomenclature of these conditions which produce such a variety of results. He thought both rheumatism and osteo-arthritis were microbic diseases. If ligamentous structures interfere with motion, passive motion was proper.

DR. LEE was reminded of a case which was at first thought to be spinal myalgia, but which proved to be gouty disease of the cartilages, an infrequent affection. Apparatus afforded relief, but of course not a cure.

DR. RYAN said that gouty spondylitis is generally attended by manifestations in other parts of the body. He had failed to state that his patient had limited respiratory movements.

DR. VANCE related a case in which there was, in addition to the spinal affection, complete immobilization of the thorax, with chiefly diaphragmatic respiration.

DR. BARTOW had seen a case in which relief was afforded by the spinal jacket.

DR. GILLETTE reported a case which, at the first glance, resembled the deformity of Pott's disease, but which proved to be rachitic in its etiology. Improvement followed a few days after suspension was begun.

TORTICOLLIS.

DR. WHITMAN inferred, from the study of 264 cases, that torticollis was more frequent in females than in males, and that the two sides of the neck were equally liable. Acquired torticollis, being often the result of suppurating cervical glands, should be treated at first by mechanical support to secure rest and prevent deformity. Later, division of contracted parts, with careful after-treatment, should be practiced.

DR. HOFFA said that cases of foetal origin have immediately after birth an atrophy of the face and head.

DR. WHITMAN thought that the asymmetry of the face and head was a late feature of torticollis due to muscular action on the growing bones.

SACRO ILIAC DISEASES.

DR. LEE said the sequence of events is as follows: 1. Injury of the synchondrosis. 2. Sub-acute inflammation. 3. Irritation of the nerves of the joint, transmitted to the nearest plexus. 4. Resulting pain in the sciatic. The sciatica should be considered the result, not the cause, of all the trouble. In nine cases out of ten, neuralgia is the effect and not the cause of any trouble. As stooping in sacro-iliac diseases is injurious, he had devised a handy instrument with which the patient can pick up an object from the floor while remaining erect.

ELECTION OF OFFICERS.

DR. BENJAMIN LEE, of Philadelphia, was elected President, and DR. JOHN RIDLON, of New York, Secretary, for the ensuing year.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

In the official report of Drs. C. F. MacDonald and Samuel S. Ward, the physicians appointed to supervise the four electrical executions at Sing Sing Prison in July last, which has just been made public by the Superintendent of State Prisons, many points of interest are to be found. In the killing of Slocum, the first man executed, a pressure of 1,458 volts, through electrodes in contact with forehead, temples and left leg, was applied continuously for twenty-seven seconds. When the current was broken, an examination showed that the pulse was beating strongly, and one or two minutes later, a noisy and regular respiration was established. The same

pressure was again applied for twenty-six and one-fourth seconds, at the end of which time life was completely extinct.

In the case of the next man executed, Smiler, a pressure of 1,485 volts was applied three times for periods of ten seconds, with brief intervals intervening, and between each of the three periods the electrodes were freshly moistened. At the end of the third application, the pulse was found to be beating so firmly and strongly that, although no effort was made at respiration, the circuit was again closed for nineteen seconds, when the man was declared dead. In the case of the third man, Wood, three contacts of twenty seconds each were made, and an examination then showed that respiration had permanently ceased, while no pulsation could be felt at the wrist, and no heart beat could be detected on auscultation. An extremely fine, faint crepitation could be heard, but nothing else. As in the preceding instance, the pressure was 1,485 volts. In the case of Jugiro, the fourth man, a like pressure was applied three times for fifteen seconds, with intermissions of twenty seconds each. When the current was finally broken, a very slight fluttering could be felt at the wrist. Extreme heat was noted in the region of the knee, just above the point where the lower electrode had been applied, and a thermometer held against the skin for only fifteen seconds ran up to 115°, while the sensation conveyed to the hand was such as to render it probable that the temperature had reached, if not exceeded, the boiling point of water. Within fifteen minutes after the withdrawal of the current the chest was bared, and the cessation of the heart-beats confirmed.

As in the brief report to the warden of Sing Sing Prison, published shortly after the execution, the physicians express their positive conviction that unconsciousness was instantaneous and continuous from the first moment of contact in each instance. In order, however, to ensure that death supervene as speedily as possible, they think it is necessary to continue a current of the voltage employed in these cases for from fifty to sixty seconds. In each case the temperature of the water near to, and at the edges of the electrodes, was raised nearly, if not quite, to the boiling point, so as to blister the skin more or less extensively. There was absolutely nowhere any smoking, charring or burning.

Before going to the Medical and Surgical Congress, and after their return from Washington, Sir William and Lady MacCormac were the guests of Dr. Lewis A. Sayre here, and on Wednesday, September 30, at Dr. Sayre's hour, the distinguished London surgeon gave a clinical lecture in the amphitheatre of Bellevue Hospital, during the course of which he performed an excision of the elbow-joint. Dr. Sayre's myriad friends throughout the country will be glad to hear that, notwithstanding the gratuitous and malicious report published a short time since in one of the morning papers, that he was hopelessly invalided and had permanently retired from practicing and teaching, he has quite recovered from his severe illness, and has once more regularly resumed his valued instructions in connection with the chair of orthopaedic surgery at Bellevue.

In addition to "Laloo, the double-bodied Hindoo boy," there is at present on exhibition in this city a remarkable double-headed and double bodied monstrosity that was with Barnum when he had his show in London, but has never been in America until now. In this instance, while there are two entirely separate heads and pairs of shoulders and upper extremities, the bodies are united for a short distance, the right and left axillæ respectively to a little above the hips, and from there down there is but the body of one person. There is complete use of the four arms, which are well developed, but the legs are not sufficiently strong to bear the weight of the parts alone without some additional support to supplement them. The sex is male and the two boys are said to be possessed of more than average mental capacity. Their faces are bright and intelligent, and they speak French and Italian fluently. Consciousness and sensation are entirely separate in the two, and one may be sleeping while the other is awake. Curiously enough, one lower extremity seems to belong to each boy exclusively; so that the boy on the right feels no sensation when the left leg is pinched or pricked, and the boy on the left is unconscious of any irritation applied to the right leg. These conjoined boys were born in Italy sixteen years ago, and their mother, Antonia Battista, a stout, healthy woman of 36, accompanies them here. The day of their birth was the 4th of July, and they might with propriety have been named after George Washington and Thomas Jefferson; but as their parents were probably ignorant of the significance of that glorious anniversary, they were christened simply Giovanni and Giacomo.

In connection with the St. Thomas House, with its meeting hall, school-rooms, work-rooms, library and gymnasium, the noble charity which Mr. Flower, the Democratic candidate for Governor, founded and endowed as a memorial of his son, there is a well appointed diet kitchen. This is conducted by the "Helping Hand Society," with a hired matron in special charge, and large quantities of beef tea, mutton broth, and other articles of nutriment are dispensed from it to the sick poor of the parish and the neighborhood.

It is stated that the surgeons of the New York Hospital some little time since made an unsuccessful attempt at skin grafting with the skin of frogs in a case of extensive burn. Six dozen of the finest specimens to be had in the market were selected and fed and attended with the greatest care, so as to have them in the best possible condition at the time of the operation. Some thirty grafts about the size of a twenty-five cent piece, taken from the backs of as many well fattened frogs, were used at one time, and it seemed at first that there was every prospect of success. The final result, however, was a total failure, as the grafts were not possessed of sufficient vitality for the desired purpose. Still, it is an ill wind that blows nobody any good, and for some time the house staff luxuriated on the choicest frog legs. P. B. P.

Editor of The Journal:

Dear Sir:—I beg to ask you, through THE JOURNAL, the following questions:

1. Is a regular physician, who graduated at a reputable homœopathic college and practiced the same, but has since disavowed and refuses to practice homœopathy, and applies to the American Medical Association or any auxiliary for membership, would he be eligible?

2. In the Code of Ethics of the American Medical Association, what is meant by the term "regular?"

G. M. CLOUSE,

Sec'y Central Ohio Medical Society.

1. Yes, and given all needed professional support. Any other course would smack of the intolerance and bigotry of the dark ages.

2. The term "regular," as used in the Code of Ethics of the American Medical Association, refers to one who has graduated from a reputable medical college, and in practice conforms to the methods of professional conduct enunciated by the Code of Ethics of the American Medical Association.

MISCELLANY.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.—The fourth annual session of the Southern Surgical and Gynecological Association will be held in the Hall of the House of Delegates, in the city of Richmond, Va., on Tuesday, Wednesday and Thursday, November 10, 11 and 12, 1891, under the Presidency of Dr. L. S. McMurtry, of Louisville. The Secretary, Dr. W. E. B. Davis, of Birmingham, Ala., is arranging a full and interesting programme, and the Chairman of the Committee of Arrangements, Dr. Hunter McGuire, of Richmond, announces that the facilities for a successful meeting are complete. This Association is essentially a working organization, and is doing a great work in the Southern States. The three volumes of Transactions already issued are highly creditable to any society or country, and have elicited the highest commendation from the medical press in this country and Europe. The meeting in Richmond promises to be the most successful the Association has held. Members of the profession generally are cordially invited to attend.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from October 3, 1891, to October 10, 1891.

Surgeon William H. Forwood, U. S. A., granted leave of absence for one month, on account of sickness.
Col. Charles T. Alexander, Chief Medical Purveyor U. S. A., relieved from duties of attending surgeon and examiner of recruits in New York City, and assigned to the charge of the medical purveying depot in that city.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending October 10, 1891.

Surgeon S. H. Dickson, ordered to Marine Bks., Washington, D. C.
Surgeon A. Magruder, detached from Marine Bks., Washington, D. C.
Surgeon N. McP. Ferebee, ordered to the U. S. S. "Atlanta."
Surgeon M. C. Drennan, detached from the U. S. S. "Atlanta."
Surgeon J. R. Tryon, ordered to the U. S. S. "Chicago."
Medical Inspector J. C. Walton, detached from the U. S. S. "Chicago," and granted six months leave.
P. A. Surgeon J. F. Keeney, from the U. S. S. "Minnesota," and to the Naval Hospital, New York.
P. A. Surgeon R. P. Crandall, from the Naval Hospital, New York, and to the Naval Laboratory.
Asst. Surgeon Robert Boyd, from the Marine Rendezvous, Boston, and to the U. S. S. "Chicago."
Asst. Surgeon A. R. Alfred, from the U. S. S. "Fern," and to the U. S. S. "Kearsarge."
Asst. Surgeon M. F. Gates, from the U. S. S. "Kearsarge," and to the U. S. S. "Fern."
Surgeon Howard E. Ames, ordered as delegate to the Public Health Association, Kansas City, Mo., October 20, 1891.
Asst. Surgeon James H. North's resignation accepted September 8, 1891.

SECTION OF ORAL AND DENTAL SURGERY.

(Concluded from page 602.)

DISCUSSION ON DR. MARSHALL'S PAPER ON THE RHEUMATIC AND GOUTY DIATHE- SIS, AS MANIFESTED IN DISEASES OF THE PERIDENTAL MEMBRANE.

Dr. Williams:—Mr. Chairman, I have a few words to say, and that is that this paper seems to me to be a very sound and rational paper in every respect. There is a point of originality in the cause of secretions which strikes me as quite new. Another point that I fully concur in is that the local treatment, whether by ploughing with instruments or by application of various medicaments, will not produce the preventative action we want.

Dr. Noble:—I was very much interested in one or two points in the paper, and that was the source of this deposit that we find frequently in these deep seated troubles, and I know that we want to seek for something besides a local cause. I was very glad to see a proof of Dr. Marshall's ability in that direction. I have not much to say because this is rather a new thought to me in looking for these troubles; but I shall in the future try to observe some facts drawn out by Dr. Marshall's paper. I have not the slightest doubt but they are derived from correct observation. I think we must look to the system far more than we have looked in general treatment. It is rather in the general system than in local causes that we should look in many of the most marked and deep seated troubles. I rejoice to see a paper with the perfection with which this paper was placed before us, and shall read its publication with a great deal of interest; and try to see if the statements made by Dr. Marshall can not be verified by observation in my own practice.

Dr. Whitefield:—I would like to say a few words about a case that bears on this subject.

I have in mind a patient who came to me seven years ago with almost perfect teeth, but her gums were highly lacerated. The explanation she gave was that she used to have a desire to probe her teeth continually and thought that caused the trouble. At the time I did not understand how to treat her; but later on I found the lady was suffering from a rheumatic diathesis, and every once and awhile this would occur. As I knew her better, I now can recall that she would have this trouble about the time she would have the rheumatic trouble. She was past the middle period of life and had almost perfectly sound teeth. She was very cleanly about her teeth and I never could find a particle of tartar about her teeth. I am therefore confident that Dr. Marshall's deductions are correct.

Dr. Daniels:—I would not attempt to discuss a paper like this without some preparation. I certainly think that in all of these papers there ought to be some time allowed for criticism. I have no doubt, from the style of the paper, that Dr. Marshall has given a great deal of thought to it, and thought that will lead in the right direction and that we should learn more about the manner of investigating this very serious trouble. I would like to hear others on the same subject.

Dr. Taft:—Gentlemen, I have had a great many ideas on this subject in my time, some of which I think were good, and some of which I thought at the time were good, proved afterwards not to be very good; a variety of ideas. In reference to these particular deposits upon the root of the tooth in connection with the suppuration that takes place between the root of the tooth and its surrounding tissue in the disease of the periosteum, or tissue surrounding the cementum, it is found in various forms as you all know. Sometimes it is more dense than ordinarily. Sometimes there is a considerable amount, in thick clumps, and in some cases largely distributed over the root of the teeth. I think it is always of a darker color than ordinary salivary calculus. There are a great many varieties and it will be interesting to follow them out and the paper leading in that direction. It would be an interesting question to decide fully by induction the action of these various presentations of this trouble. The deposit is sometimes very rough

on its surface, in other instances quite smooth. However it may be in these respects, it presents a surface in which the tissue can never unite, and while it remains there will necessarily be a diseased condition. That it comes from the saliva there is no evidence whatever, as indicated in the paper. It was formerly assumed by many that it occurs in the same way that ordinary saliva calculus does; but there are so many counter-indications, that this theory can not be considered as correct; and we must look for the trouble elsewhere. I have no doubt this material is a deposit from the blood. Where this disease takes place, how this disease begins, perhaps is not so easily explained; that is, how the disease occurs in connection with this condition of affairs. As a matter of course there must be an irritant in the part before any deposit takes place; that this deposit is a primary thing in this respect I do not believe. I think it is a consequence of the diseased condition that existed before any deposit at all was formed. What the irritant or cause of this disturbance is in the first place, I will not now pretend to say; only that it is at first a point of deposit, a point upon which vicious matter is retained, that becomes more and more vicious as it remains. Dead material that comes into such a pocket or space will be more likely to be retained on this roughened surface. It occupies the place that living tissue ought to occupy, and then again where it is rough, and sometimes it is found very rough, it consists of little nodules all over the surface. Allowing the tissue to come in contact with it will create irritation. There will be irritation induced by pressure against it, and when there is a rush of blood to the part, an enlargement of the vessels in the immediate vicinity thus occurs. This sensation has been referred to by Dr. Marshall, that persons desirous of assuaging pain will do so by pressure upon the teeth, and that will give relief. By pressure it relieves the distended vessels, and then by letting up again there is a sense of relief.

Well, then, the question occurs, what shall be done; mere systematic treatment will not do. I do not believe that after this deposit has been made upon the roots of the teeth that it can be removed by systematic treatment. It is true, that if the system is in bad condition it may be improved, and whatever may be done in that respect increases the tone and strength, and often relieves the system of embarrassment of this kind; although it will not remove this particular deposit. It is sometimes confined to the end of the root and there may be very little of a pocket. Sometimes it may be found on teeth on one side, sometimes at the end; in molar teeth it is often in the bifurcation of the roots. Its frequent point of deposit in such locations renders it exceedingly difficult to remove, as this material

does not readily dissolve by solvents; that is, where there is a large mass of it, it is not readily dissolved. In testing the solubility of this material in sulphuric acid it does not readily dissolve; so that what should be done with it is a question that is difficult of solution. If there is a pocket running down, it may be removed with a fine chisel-shaped scaler; but what shall be done when there is no pocket, when there is not a large space around the edge of the root. I have not long since seen superior molars removed with three well-defined roots, in which, at the bifurcation, there were large masses of this material. In a case of mine where the patient was exceedingly anxious to save the tooth, which we always try to do when we can, he had given it treatment both surgically and with applications; but the tooth had to be taken out. Upon the outside of the roots where they could be reached with a scaling instrument they were in good condition, but where the surfaces were inaccessible by the instrument, sulphuric acid had been used, but with very little effect. Now a case of this kind is very difficult to manage.

Another point is, what shall be done in the way of prophylaxis, before any disease has taken place? Can any treatment be employed before other disease commences? Are there any indications, are there any symptoms in the beginning that will aid you, and for which remedial or preventive treatment may be employed? These are points to which attention ought to be given and which we ought to study as thoroughly as possible in order to attain to an effective treatment or management of such cases. When we speak of prophylaxis, I suppose we speak of management of the body in such a way as to divert or prevent disease. What can be done to prevent this, and when that is ascertained what treatment may be employed to prevent or cure this condition? I fancy that we do not sufficiently understand the beginning of diseases of the teeth, and that therefore our prophylactic treatment and suggestions with reference to prophylaxis is quite below what it ought to be, and what it ought to be for the best interest of our patients.

What light ought we to have on this subject?

Dr. Whitefield:—It seems to me that the value of Dr. Marshall's paper is that it does not point out treatment except in a general way. The question we ought to know is whether persons with rheumatic diathesis are more liable to have trouble.

Dr. Marshall:—Mr. President, I purposely avoided in my paper any reference to a special method of treatment. My idea was to present a paper on the pathology of the condition; and of course, as the title of my paper indicates, I confined it to the manifestation of rheumatic and gouty diathesis as manifested in diseases of the periodontal membrane. In reply to Dr. White-

field's question I may say that I have never noticed any difference between living and dead teeth so far as the manifestations in the periodontal membrane are concerned. The remarks of Dr. Taft deal very largely with the point brought out in the paper with regard to location of concretions on the teeth and their character. Dr. Noble asked a question which I do not think was fully understood; whether these concretions were found at the apex or upon the root of the teeth where there was no external opening at the margin of the gum, which proves, I think, my position. I claim such conditions exist as a result of rheumatism and gout, viz: that the concretions are not of salivary origin. The issue I take with Dr. Ingersoll is, that these deposits are not necessarily the result of suppuration, or that lime salts are deposited as the result of inflammatory conditions. I claim, on the other hand, that the concretions just referred to are the results of a rheumatic or gouty diathesis, and are deposited upon the cementum through the agency of the peri-cementum, just as concretions are deposited in the synovial membrane in rheumatic arthritis. I have never seen a case which I classify as rheumatic without finding concretions present; but phagedenic peri-cementitis is not always the result of a rheumatic or gouty diathesis. You will find a great many cases of phagedenic peri-cementitis in which the roots of the teeth are perfectly clean. To illustrate, and I mentioned this in a discussion some years ago before the American Dental Association at Minneapolis, phagedenic peri-cementitis is often the direct result of peculiar neurotic conditions of the system. I recall the first case of this character that came under my notice, a patient with facidental peri-cementitis. When the patient came into my hands I tried to find concretions upon the roots of the teeth, but could find none, and I was at a loss to explain the difficulty. I made up my mind after careful study that it was a neurotic condition, or at any rate a reflex nervous condition that affected the general health, and suspected from certain symptoms that she was suffering from some uterine displacement, so sent her to a specialist with the request that he would thoroughly examine the case. He reported that she had an anteversion of the uterus and replaced it; and in less than three months her mouth was well. All the treatment she had at my hands was an antiseptic mouth wash, and the replacement of the uterus by the specialist. I have noticed also other cases in which individuals suffering from diseased conditions of remote organs had this same condition of the teeth. Phagedenic peri-cementitis is often associated with Bright's disease and diabetes mellitis. Concretions upon the roots, however, are the most common cause that produce this condition of the peri-cementum.

Dr. Taft:—What is your opinion in regard to

the presence of these secretions in inflammatory cases?

Dr. Marshall:—I claim the concretions are the cause of the inflammation; they are the result of the peculiar diathesis of the system, and not the result of the inflammatory action. We find in the synovial membranes that acid crystals are deposited there and by their presence cause irritation. We sometimes find associated with these crystals the calcium salts; and the longer the disease has been running, the more likely is it that we find this peculiar condition of the concretion, that is the presence of lime salts. I have not been able yet to demonstrate by chemical analysis whether or not the concretions upon the roots of the teeth are really made up of urate of soda and lime salts. I hope sometime to be able to make the analysis; and if I get hold of a case in which the teeth must be extracted and I am sure the disease is caused by this rheumatic diathesis, I shall submit it to the best chemist we have in Chicago with instructions to examine thoroughly and report as to its composition. That is the only way to prove the theory that I have advanced.

Dr. Whitefield: Do you not consider that there may be soreness long before actual deposition?

Dr. Marshall: That is one of the general symptoms of this rheumatic or gouty condition of the system. You will find in scores of cases that the very first symptom of rheumatic trouble presented will be soreness of the teeth. In a great many cases they do not progress beyond the stage of congestion, which simply results in soreness and thickening of the membrane; a great majority, however, of the chronic cases result in exostosis of the roots and in enlargement of the epiphyseal ends of the long bones. The cases in which there are pus pockets formed are comparatively small in comparison to those that result in periodical soreness of the teeth, with thickening of the periodontal membrane.

Dr. Williams: I hope Dr. Marshall will report after he has made the experiments.

Dr. Marshall: Another point I would like to mention is that in regard to the systematic treatment. I indicated in my paper that in a great number of these cases I analyzed the urine and found that the uric acid was largely in excess. In a case of this kind, I would say to my patient you are living too high, my friend, again; you will have to cut off your wine and eat no more meat, but be a vegetarian; and just as I restricted him in these things his symptoms improved. This class of cases are just as amenable to systemic treatment as the ordinary cases of inflammation of the joints. If you take it early enough you can control the symptoms; and it was this fact, as I mentioned in my paper, which led me up to the thought which I have presented with regard to the origin of many of these affections.

Dr. Whitefield: The last point is where the value of your paper lies.

(Here Dr. Taft read his paper on the "Care of the Teeth.")

Dr. Whitefield: This is a subject that interests me very much. I have always thought that a man's position depends very much on the way he regards itself. A dentist may be what I may call a scavenger, or he may not, just as he pleases. I certainly would never do any of this kind of work. If a man comes to me with his mouth filthy, I will tell him in as delicate a manner as possible to go home and cleanse his mouth; and if this is done rightly he will not take offense. I have seen cases where the mouth is so filthy that I would not handle it under any circumstances. I will point out to them and tell them what harm they are doing their teeth by letting them get in that condition. I find in most cases that when such people come back they have their mouths in good condition; they have thought about what I said. I impress upon them this point that if they will do their part, I will do mine; otherwise I will not do their work. I charge good fees, and my patients expect to have good work done. If they follow my instructions my work will stand and will be a credit to me. I think this matter should be emphasized more than it is by every dentist.

Dr. Williams:—I am very glad that Dr. Taft read that paper, because he refers so strongly to the necessity of dental hygiene and about the frequent neglect of dental hygiene. How often do we find teeth to fail even when well filled, because the general health of the mouth is neglected. Why is it? I think I can point out part of the reason why it is. It is because a man calls himself simply a dentist and thinks that all he has to do is to attend to a particular tooth. The fact is that he ought to be qualified so as to take just as good care of the health of the mouth. We should be orists. That is the proper name for an educated practitioner. As Sir Morrell Mackenzie says, the mouth is the gate of life; we stand guard over that mouth and not simply over the posts, or whatever you call them. We take charge of the whole mouth. If we have a pride in considering ourselves orists, I think we will naturally take a higher standpoint of vigilance than is generally taken.

Dr. MacNaughton:—The university from which I have the honor of being graduated impressed this on the students, that we have the right and privilege to charge whatever we think our services are worth; one of these services is to cleanse the teeth perfectly. The perfect cleansing of the mouth of a patient often does them more good than anything we can do for them. I have frequently advised my patients to cleanse their teeth, but if they will not do it I will do it myself and think it will redound to the

credit of the profession and educate the public.

Dr. Whitefield:—I thoroughly agree with the lady. What I meant to say was that where I could induce my patients to cleanse their mouths themselves I would do so.

Dr. Taft:—The conservation of the health of the mouth is a great matter; the preservation of it in the best possible condition to resist diseases of the tissue of the mouth. The mouth is the territory of the orist; it is the territory which is committed to his care, and he must do whatever he can to promote its best interests and he ought to be able to know and understand the condition and whatever is necessary to improve them. It is vastly better to preserve teeth and the mouth in a condition of health, usefulness and comfort, than it is to restore them after the incursions of diseases; and this is just the point I make, that this matter is overlooked. You will often treat a tooth to secure a good condition for life perhaps, whereas if neglected ruin would ensue so far as the tooth is concerned. It is to arouse attention to this subject that I have prepared this paper.

Dr. Williams then gave a brief epitome of his paper, "Remarks on Incipient Necrosis and Caries;" there not being time to read it, after which the session was adjourned sine die.

PHARMACOPŒIAL NOMENCLATURE, AND THE LATIN OF PRESCRIPTIONS.

Read before the Section of Materia Medica and Pharmacy, at the Forty-second Annual Meeting of the American Medical Association, Washington, D. C., May 1, 1891.

BY PROF. JOS. P. REMINGTON, PH.M.,
OF PHILADELPHIA, PA.

The frequent recurrence in current secular literature, and in halls of legislation, of the agitation against the use of Latin in prescribing and designating medicinal substances has developed a need for a strong expression of the well known advantages of the use of the Latin language in nomenclature.

The pharmacist, because of his familiarity with the methods employed by many physicians, and on account of the large number of prescriptions which annually come under his critical observation, has by far the best opportunity for forming an accurate opinion of the relative value of the methods used in writing prescriptions, and the consensus of opinion is vastly in favor of retaining Latin.

By far the larger number of prescriptions which are now compounded in the United States are written in Latin, but occasionally it will be found that a physician has formed the habit of writing in the vernacular.

The general acceptance by the medical and pharmaceutical professions of the nomenclature

of the Pharmacopœia during the last half century, has had much to do with the improvement noticed in the language of prescriptions, and although it is common to hear unfavorable criticisms as soon as a new Pharmacopœia is issued, about the inconvenience of alteration in nomenclature, especially when well established names have been changed; yet when improvements are made that must upon second thought be universally acknowledged as such, and particularly when the revisions which are carried out recognize the cardinal principles of simplicity, uniformity and accuracy, then, and then only, can the changes be cheerfully welcomed.

The first Pharmacopœia, published in 1820, presents some curious illustrations of defective nomenclature; for instance, the name aqua potassæ was applied, in the same book, to two official preparations, one aqua potassæ on page 82, made by dissolving one ounce of bicarbonate of potassium in a gallon of water and saturating the solution with carbonic acid; the other, on page 188, corresponded with our present liquor potassæ, and was a caustic solution sixteen times stronger than the other aqua potassæ.

The various committees of revision which have been appointed at every decade since then, have successfully wrestled with the subject of the nomenclature, advances being made at each revision, but not without sturdy protests and often severe denunciation for "introducing innovations" from those who believe that the use of a bad name "once established" is to be preferred to the use of a correct name, if such involves a change.

But the committee have never been wanting in the necessary courage to make such revisions in the nomenclature as they believed were warranted at the time; they have, however, always stopped short of what they considered their ideal in deference to a wise conservatism which realized fully that the names of widely known and largely used medicines should not be changed without just cause.

The greatest number of alterations in the various revisions have been made in the names of the chemical substances in the 1870 Pharmacopœia; this was due of course to the upheaval in chemical nomenclature which occurred at that time.

The committee of 1850, however, chose to ignore the controversies of the chemists in the case of two very important substances, calomel and corrosive sublimate; it may be remembered that the equivalent of mercury, as it was then called, was variously stated by chemists as 100 and 200; this gave rise to serious differences in nomenclature. If 200 was regarded as the proper equivalent, then corrosive sublimate became the bi-chloride of mercury, and calomel would be the chloride or proto-chloride of mercury; whilst, if 100 was regarded as the correct equivalent, cor-

rosive sublimate must be considered to be the chloride of mercury, whilst calomel would be the di-chloride, or sub-chloride.

It will then be seen that whenever a physician ordered chloride of mercury in prescriptions, the apothecary was always put to the necessity of guessing whether calomel or corrosive sublimate was wanted; this embarrassing and often dangerous situation in nomenclature was satisfactorily cured by the committee of 1850, who adopted names for the mercurials in which the distinctions were based upon their physical properties rather than their chemical composition, and the official name for calomel became hydrargyri chloridum mite, and that for corrosive sublimate, hydrargyri chloridum corrosivum; in the case of the iodides of mercury the difficulty was overcome by Latinizing the colors of the two salts, and hydrargyri proto iodidum became hydrargyri iodidum viride, and hydrargyri deuto-iodidum was changed to hydrargyri iodidum rubrum.

These names have now become established, and they are not likely to be changed in one generation.

Old physicians will continue to use these ancient names, and it frequently becomes a question of serious importance to the pharmacist to know when hydrargyri chlor. is directed, just what to dispense; this is particularly difficult to judge at the present time, when the doses of calomel seem to be growing infinitesimal, and the former wholesome fear of corrosive sublimate seems to be greatly disappearing in the light of its extensive employment.

The various colleges of medicine are of course doing excellent service in teaching students the pharmacopœial nomenclature, and each succeeding generation of physicians will largely use the improved forms, but a careful inspection of an active prescription file will show that a large number of antiquated terms are still in common use.

The marvelous growth in the number of substances introduced into the *materia medica* during the last decade, particularly in synthetic products which possess antipyretic or sedative properties, and the astonishing progress made in developing chemical industries devoted to the manufacture of special products of more or less value, has had a curious effect upon the system of nomenclature which is now generally accepted; of course it has long been established as an axiom that the chemical name of a substance should accurately define its constituents, and in simple or binary compounds this rule meets with no obstacles; the fact that the substance known officially as ferri iodidum, iodide of iron, or its synonym ferris iodide, is composed of certain proportions of iron and iodine, is an illustration of the beautiful simplicity of the method which every tyro in chemistry is perfectly familiar with; but when

it is recognized that the treatment of disease cannot be cribbed and confined by the use of such easily named and readily understood remedies, and that now such ponderous looking compounds as Diethylsulphondimethylmethane, acetophenone, phenylacetamide, para-acetphenetidine, phenylhydrazinelevulinic acid, phenyldimethylpyrazolon, therahydroparaquinanisol, methylterhydro-oxyquinoline, carbonate of sodium, are in common use for the simple operations of lowering the temperature, diminishing the frequency of the pulse, or inducing sleep.

It is true that the manufacturer soon recognized the practical difficulties in the way of prescribing such remedies by their correct chemical names, and that it was easier for a physician to write instead sulphonal, hypnone, antifebrine, phenacetine, antipyrine, antithermine, thalline, thermifugin; and then again it was *easier* to obtain a copyright for an original name devised for the purpose, and thus the monopoly for its manufacture could be securely protected.

It is unfortunate that some simple yet descriptive nomenclature cannot be devised for this class of complex substances which are now so largely employed.

It is, however, in the naming of plants and vegetable drugs that the present official system is seen to the best advantage, and the value of such simple names as opium, buchu, calumba, etc., is enhanced by the simplicity of the titles of preparations made from them as *tinctura opii*, *extractum buchu fluidum*, *infusum calumbæ*, etc.

In those instances which sometimes occur, where two or three plants are indiscriminately used under one name, the pharmacopœia, by its description, carefully designates the plants which may be used. For an illustration, the case of *rubus* may be cited, which is described as "the bark of the root of *rubus villosus*, *rubus canadensis* and *rubus trivialis*," thus showing that the root from either or all of these plants may be employed; but for *lobelia* but one *lobelia* is recognized, *i. e.*, *lobelia inflata*, the species *syphilitica* and *cardinalis* not being accepted as of equal value; and it is in connection with the vegetable drugs that the merit of a well-defined and carefully considered system of Latin nomenclature is conspicuous.

The Latin name of the plant is almost always well established by botanists, and is not liable to change. Of course, plants which are of comparatively recent discovery may be attributed to incorrect sources, and subsequent revision is needed; but what shall be said about the common English names of plants, and what dire results would flow from the practice of prescribing through the use of these names.

A few years ago an editorial appeared in an influential daily newspaper, stating that the Legislature of the State of Pennsylvania would be

asked to pass an act requiring physicians, and all other persons engaged in prescribing medicines or drugs for the sick, to write the names, quantities and designations of the same plainly, in the English language and without abbreviations, and that all druggists, vendors, or compounders of drugs, medicines or herbs for the use of the sick, shall be required to label or print the names thereof conspicuously on the outside of the bottles, pots or packages containing the same, in the English language and without abbreviations.

Since this act was framed, in a number of other States, similar legislation has been sought, and the arguments used by the worthy editor of the newspaper so clearly present the views of those who sincerely believe in such legislation, that a few extracts are inserted:

"The intent of the proposed act is to prevent the poisoning of people by the blundering clerks of druggists. Any reform which will tend to reduce the chances of error deserves commendation, and especially so if it is a reform that is proposed in conformity with the requirements of common sense. There is no considerable reason why an *American* physician, who wishes to order medicines from an American drug store, should express his wish in mutilated fragments of a dead language. The drug clerk can understand his own language much more easily than he can interpret Latin abbreviations. Only one excuse for the retention of the dog-Latin prescription can be imagined, and that is an excuse which neither physicians nor druggists are likely to present. It is that doctors sometimes do not care to have their patients know what medicines have been prescribed. One of the first natural rights of a human being, however, is to know what is the name of a substance that is put into his own body; and he has the right to know what medicines he is taking, even if he is unable to comprehend their purpose and operation."

This editor was finally induced to change his views, and the act was pigeonholed, but the means by which it was accomplished did not reflect much lustre upon his heroic efforts to unselfishly serve the interests of the dear public.

To all statements that the exclusive use of the vernacular would result in disaster he turned a deaf ear. He was shown a long list of drugs, the names of which were used synonymously for widely different substances, and informed that the very fact of Latin being a dead language, and thus not subject to change, and that it was understood in all civilized countries, being the universal language of science, were strong reasons for retaining its use; and all of the well-known arguments were in turn used unavailingly upon him, until at last it was pointed out, that if physicians' prescriptions were hereafter to be written exclusively in English, and if the prescriptions must be transferred to the label, so that every patient could see

exactly what he was taking, that the act, in strict justice, would also compel the printing of the *exact constituents of every patent medicine, upon their labels*; for, if it is necessary for the public protection to have the ingredients of a prescription which has been ordered by a responsible physician, to serve a special purpose, written on the label, of how much more importance does it become, to have the constituents of a secret, so-called, remedy, which is *taken by the patient without skilled advice, placed where the patient can read as he runs*, and when it was also pointed out that this would probably reduce the patent medicine business to bankruptcy, and largely diminish the advertising patronage of the manufacturers, for his newspaper, he promptly declared the act that he had so vigorously defended previously, unwise and probably unconstitutional.

Since the occurrence of the incident above mentioned, there have been several spasmodic attempts at legislation in favor of abandoning Latin in prescriptions, the last effort that the writer is acquainted with being that attempted during this last winter, in the State of Texas.

With the view of illustrating some of the dangers and annoyances that would arise, in case legislation should ever be effected, the following list of substances used under different names in different parts of the country is submitted:

Alum Root may be either *Heuchera Americana* or *Geranium Maculatum*.
 American Sanicle may be either *Heuchera Americana* or *Sanicula Marilandica*.
 American Valerian may be either *Cypripedium pubescens* or *Polemonium reptans*.
 Ash, Prickly may be either *Xanthoxylum fraxineum* or *Aralia spinosa*.
 Balm, Sweet may be either *Melissa officinalis* or *Dracontium canariense*.
 Balsam, Sweet may be either *Gnaphalium polycephalum* or *Impatiens balsamina*.
 Bay Tree may be either *Myrica cerifera* or *Laurus nobilis*.
 Bears Foot may be either *Dracontium foetidum* or *Helleborus foetidus*.
 Beech Drop may be either *Orobancha Virginiana* or *Epiphegus Americanus*.
 Bird's Nest may be either *Daucus carota* or *Monotropa uniflora*.
 Bitter Clover may be either *Sabbatia angularis* or *Centaurea Americana*.
 Bitter Wood may be either *Simaruba excelsa* or *Quassia excelsa*.
 Black Cohosh may be either *Cimicifuga racemosa* or *Macrotys racemosa*.
 Blazing Star may be either *Aletris farinosa* or *Helonias dioica* or *Liatris squarrosa*.
 Blue Cohosh may be either *Caulophyllum thalictroides* or *Leontice thalictroides*.
 Bowmans Root may be either *Gillenia trifoliata* or *Euphorbia corollata* or *Leptandria Virginica*.
 Bugle Weed may be either *Lycopus Virginicus* or *Lobelia inflata*.
 Bugloss may be either *Anchusa tinctoria* or *Borago officinalis*.
 Button Snakeroot may be either *Liatris spicata* or *Eryngium aquaticum*.
 Cancer Root may be either *Epiphegus Americanus* or

Orobancha Virginiana. *Phytolacca decandra*.
 Catch Fly may be either *Apocynum androsaemifolium* or *Silene Virginica*.
 Checker Berry may be either *Gaultheria procumbens* or *Mitchella repens*.
 Clover, King's may be either *Melissa officinalis* or *Melilotus alba*.
 Colic Root may be either *Dioscorea villosa* or *Asclepias tuberosa*, or *Aletris farinosa*, or *Helonias dioica*, or *Liatris spicata*.
 Collard may be either *Dracontium foetidum* or *Symplocarpus foetidus*.
 Coltsfoot may be either *Tussilago farfara* or *Asarum canadense*.
 Corn Snakeroot may be either *Eryngium aquaticum* or *Liatris spicata*.
 Cure-all may be either *Geum Virginianum* or *Melissa officinalis*.
 Eye Bright may be either *Lobelia inflata* or *Euphorbia ipecacuanha*.
 Five Fingers may be either *Potentilla canadensis* or *Panax quinquefolia*.
 Golden Seal may be either *Hydrastis canadensis* or *Frasera verticillata*.
 Gravel Plant may be either *Epigaea repens* or *Galium aparine*.
 Hardhack may be either *Spiraea tomentosa* or *Collinsonia canadensis*.
 Heal-all may be either *Collinsonia canadensis* or *Prunella Pennsylvanica*.
 Horse Weed may be either *Collinsonia canadensis* or *Eriogon canadensis*.
 Indian Hemp may be either *Apocynum cannabinum* or *Cannabis indica*, or *Asclepias incarnata*.
 Indian Lettuce may be either *Frasera walteri* or *Coculus palmatus*.
 Indian Paint may be either *Sanguinaria canadensis* or *Hydrastis canadensis*.
 Ipecacuanha may be either *Cephælis ipecacuanha* or *Podophyllum peltatum*.
 Itch Weed may be either *Veratrum viride*, or *Helleborus Americana*, or *Verbascum thapsus*, or *Symplocarpus foetidus*.
 Jacob's Ladder may be either *Smilax peduncularis* or *Polemonium reptans*, or *Pulmonaria officinalis*.
 Lady's Slipper may be either *Cypripedium pubescens* or *Impatiens balsamina*, or *Variolaria faginica*, or *Valeriana officinalis*.
 Lungwort may be either *Pulmonaria officinalis* or *Variolaria faginica*.
 Masterwort may be either *Angelica atropurpurea* or *Imperatoria ostruthium*.
 Matico may be either *Piper angustifolium* or *Artanthe elongata*.
 Milk Weed may be either *Asclepias tuberosa*, *Apocynum androsaemifolium*, or *Euphorbia corollata*.
 Monkshood may be either *Aconitum napellus* or *Leontodon taraxacum*.
 Partridge Berry may be either *Gaultheria procumbens* or *Momordica balsamina*.
 Pellitory may be either *Anacyclus pyrethrum* or *Xanthoxylum fraxineum*.
 Prickly Ash may be either *Xanthoxylum fraxineum* or *Aralia spinosa*.
 Rattle Root may be either *Macrotys racemosa*, or *Cimicifuga racemosa*, or *Cicuta virosa*.
 Rattlesnake Root may be either *Goodyara pubescens*, *Nabulus alba*, *Cimicifuga racemosa*, or *Polygala senega*.
 Snake Root may be either *Cimicifuga racemosa*, *Aristolochia serpentaria*, *Eryngium aquaticum*, *Liatris spicata*, *Asarum canadensis*, *Polygala senega* or *Eupatorium aromaticum*.
 Spice Berry may be either *Gaultheria procumbens* or *Laurus benzoin*.
 Squaw Root may be either *Orobancha uniflora*, *Caulo-*

phyllum thalictroides, Cimicifuga racemosa or Macrotys racemosa.
 Squaw Weed may be either *Senecio obovatus* or *Erigeron purpureum*.
 Tetterwort may be either *Chelidonium majus* or *Sanguinaria canadensis*.
 Turmeric may be either *Curcuma longa* or *Hydrastis canadensis*.
 Water Hemlock may be either *Conium maculatum* or *Cicuta virosa*, *œnanthe phellandrium*.
 Wild Turnip may be either *Aramtriphyllum* or *Asarum canadense*.
 Yellow Root may be either *Hydrastis Canadensis*, *Coptis trifolia* or *Xanthorrhiza apiifolia*.
 Yellow Wood may be either *Xanthoxylum fraxineum* or *Aralia spinosa*.

Recently, Prof. E. M. Holmes, Curator of the Pharmaceutical Society of Great Britain, has collected some facts in connection with this subject. A few instances will suffice to show that the same English name is applied to different drugs, and to those having widely different properties. The educated English pharmacist would supply for mandrake root, that form *Mandragora officinalis*, the consumer of herbs would expect to get the root of *Podophyllum peltatum*, whilst the culler of simples understands mandrake root to be the root of *Byronia dioica*.

Again, chamomile, to the English buyer, means *Anthemis nobilis*, to the German, *Matricaria chamomilla*.

The difference in names of English and American plants is shown in the following list:

ENGLISH PLANTS.	AMERICAN PLANTS.
Adder's tongue.	Adder's tongue.
Ophioglossum vulgatum.	Erythronium Americanum.
Black alder bark.	Black alder bark.
Rhamnus frangula.	Prinos verticillatus.
Avens.	Avens.
Geum urbanum.	Geum rivale.
Bear's f. ot.	Bear's foot.
Helliborus virides.	Polymnia Uvedalia.
Birch.	Birch (or sweet birch).
Betula glutinosa.	Betula lenta.
Bittersweet.	(False) Bittersweet.
Solanum Dulcamara.	Celastrus scandens.
Blackberry.	Blackberry.
Rubus fruticosus.	Rubus villosus.
Celandine (greater).	Celandine (wild).
Chelidonium majus.	Impatiens pallida.
Centaur.	Centaur (American).
Erythraea Centaurium.	Sabbatia angularis.
Clover.	Clover (sweet).
Trifolium pratense.	Melilotus officinalis.
White Clover.	White clover.
Trifolium repens.	Melilotus alba.
Cranesbill.	Cranesbill.
Erodium cicutarium.	Geranium maculatum.
Dwarf elder.	Dwarf elder.
Sambucus Ebulus.	Aralia hispida.
Fleabane.	Fleabane.
Pulicaria dysenterica, etc.	Erigeron canadense.
Hemlock.	Hemlock (Spruce).
Conium maculatum.	Abies canadensis.
Yellow jessamine.	Yellow jessamine.
Jasminum fruticosum.	Gelsemium nitidum.
Liverwort.	Liverwort.
Marchantia polymorpha.	Hepatica triloba.
Maidenhair.	Maidenhair (Canadian).
Adiantum Capillus-veneris.	Adiantum pedatum.
Mandrake.	Mandrake (American).
Byronia dioica.	Podophyllum peltatum.
Pennyroyal.	Pennyroyal (Amer.).
Mentha Pulegium.	Hedeoma pulegioides.
Ivy.	Ivy (Amer.).
Hedera Helix.	Ampelopsis quinquefolia.
Anemone Pulsatilla.	Pulsatilla.
Queen of the meadow.	A. patens, var. Nuttalliana.
Spirea Ulmaria.	Queen of the meadow.
Ragweed.	Eupatorium purpureum.
Senecio Jacobaea.	Ragweed.
	Ambrosia elatior.

ENGLISH PLANTS.	AMERICAN PLANTS.
Raspberry.	Raspberry.
Rubus Idæus.	Rubus strigosus.
Sculcap.	Sculcap.
Scutellaria galericulata.	Scutellaria lateriflora.
Sloe.	Sloe.
Prunus communis.	Viburnum prunifolium.
Valerian.	Valerian (Amer.).
Valeriana officinalis.	Cypripedium pubescens, etc.
Vervain.	Vervain.
Verbena officinalis.	Verbena hastata.
Water lily (white).	Pond lily (White).
Nymphaea alba.	Nymphaea odorata.
Water lily (yellow).	Pond lily (yellow).
Nuphar lutea.	Nuphar advena.
Water pepper.	Water pepper.
Polygonum Hydropiper.	Polygonum punctatum.
Wintergreen.	Wintergreen.
Pyrola rotundifolia, etc.	Gaultheria procumbens.

The above illustrations will probably be sufficient to illustrate the danger of resorting to English or proper names for prescriptions, although the comments on the ludicrous mistakes that often occur from the use of medicines and pharmaceutical preparations could be extended far beyond the limit of this paper.

Per contra, it may suffice to place on record the effort of a physician who succeeded in Latinizing a very familiar name, as follows:

B. Equinæherpesamarac, oj.

Take a tablespoonful three times a day. X.

The translation is, Hos(s)tetter's Bitters.

THE PRESENT STATUS OF MATERIA MEDICA AND THERAPEUTICS.

Read before the Section of *Materia Medica and Pharmacy* at the Forty-second Annual Meeting of the American Medical Association, at Washington, D. C., May, 1891.

BY J. W. C. CUDDY, A.M., M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, BALTIMORE UNIVERSITY SCHOOL OF MEDICINE, BALTIMORE, MD.

Materia Medica and Therapeutics at present occupy an important place on the broad plane of medical science. The recent rapid growth of this department of our loved profession has been in such marked contrast with its slow development in the earlier ages that it really now excites wonder and admiration. New medicines, and new uses therefor are so prominent and so varied that it is with the greatest difficulty that any active practitioner of medicine can keep pace with them. Some of them, it is true, come up meteor-like and have but an ephemeral existence, but fortunately, many others, culled with greatest care, and evolved from the greatest scientific minds, have come to stay, and shine out as fixed stars upon the medical sky. In fact, they have now assumed such an important status that a resumé of their later growth and recent developments will certainly not be out of place in this new and important Section.

Looking back into the primary stages of medical history, and seeing the few and crude articles for internal medication upon which practitioners then depended, and then turning to the crowded shelves of our drug stores, filled with the finest preparations from our grand laborato-

ries, we can well see the advantage which we physicians now have over our fathers in the science, and congratulate ourselves that we live in so enlightened an age, and one of such great usefulness to those who require our services.

In those early days the number of drugs used were comparatively few, and their therapeutics but little understood. A few barks, a few leaves and a small number of minerals made up the medical armamentarium for the physician, while now the constituents of all the elements are at our disposal,—earth, air, and sea yielding up their richest products, which, through chemical and pharmaceutical manipulation, have become valued agents for the relief and cure of disease. Then *materia medica* was but a small department of our science. In the earlier schools it was included in the chair of Practice, and although considered an important part of the studies, it was small in comparison with others which went to make up the whole. Therapeutics was but little known, and empiricism held its sway. Thus for ages this department slumbered, until with the growth of years came the increase of medical lore. In these latter days separate and distinct chairs are established for its thorough instruction; colleges for its study alone are erected; societies are formed solely for its advancement; and magazines of the highest order are devoted entirely to its elucidation. Many of the brightest minds of this and other countries, such as Wood, Bartholow, Ringer, Biddle, Potter and others equally as eminent, have been placed at the shrine of *materia medica*, and we thank them for their devotion. And even this grand and honored American Medical Association has recently so far advanced in wisdom, as to form a separate Section "to especially consider the very important branches of *Materia Medica* and Pharmacy."

It is strange, and, in fact, we are lost in wonder, when we contemplate how little was primarily known of medicinal agents. From almost the beginning of the world, diseases and injuries existed and were known, and yet medical substances were scarcely considered. Surgery seemed then to attract greater attention, and external applications were in more general use. Starting at the onset of its history, but little is known regarding it, except the traditional accounts of the lotions and salves which were used for the healing of the warrior's wounds. But really how could material substances be known as medicinal or curative agents, when therapeutics was an unknown and untried field? Superstition held sway all through the earlier ages, even until within a few centuries of the Christian era, when through the mighty efforts of the great philosopher of Cos, the father of medicine, there was made great advancement in the science. And yet, he, Hippocrates, knew naught of the

difference between arteries, veins and nerves, and still held to the then prevalent belief that there was a spiritual restoring essence or principle within the individual himself. Within the next five hundred years Galenical ideas were superadded to the Hippocratic, and with the knowledge then of the existence of blood, and its derangements, alteratives, or blood remedies became known. From that time on, down through the centuries medical studies dragged slowly through the mists and doubts of the ages. And even with that important epoch so dear to the literary searcher, called the Revival of Learning, medical advancement was scarcely perceptible. It is true that medical studies formed a part of the curriculum of the great seats of learning in Rome, Salerno, Alexandria and elsewhere, but yet the practice of the profession was so obscured by the mysticisms of the priesthood, and the worse craftiness of the astute empirics, that it made no marked headway. True it is, that through botanical studies, new leaves and roots were brought into prominence, and the number and usefulness of drugs increased thereby. Pharmacy was, however, but little known, and crude articles measured by the ounce, or by the handful, came as near to exactness as could be then attained. It is surely then surprising that during the Renaissance when all Europe was ablaze with literary glory—when Rome was at the zenith of her fame,—when Germany had reached the transition stage from darkness into light,—when England was alive with her brilliant literature, Shakespeare singing in poetic strains grand thoughts that will never die, the slow progress of the medical profession was so marked that it is painful to contemplate the position which it then occupied.

This illiteracy or backwardness, is evidenced by the following veritable prescription, which was written by one who had attained eminence sufficient to make him the physician to Lord Bemghley, Secretary of State to Queen Elizabeth, and for whom he wrote this prescription on the ninth day of May, in the year 1553. He described it as "a goode medicine for weakness and consumption," and is as follows:

"Take a pig of nine days olde, and slaye him, and quarter him, and put him in a skillat, with a handfull of spearmiut, and a handfull of red fennel, and a handfull of liverwort, half a handfull of red neap, and handfull of clarge, and nine dates, cleaned, picked, and pared, and a handfull of great raisins, and pick out the stones, and a quarter of an ounce of mace, and two sticks of goode cinnamon, bruised in a mortar, and distill it with a soft fire, and put it in a glass, and set it in the sun nine days, and drink nine spoonfulls of it at once when you list."

Now contrast that with the position which we occupy to-day. Then huge quantities of animal

and vegetable matter was jumbled together with a "skillat" for a crucible and the sun for a chemical purifier, and after waiting for more than a week for his prescription, he was given enormous doses, or the talismanic "nine spoonfulls," at indefinite periods or "when you list." Now, through our knowledge of medical and chemical science, we are enabled to prescribe the purest alkaloid, or active principle, extracted from our most valued medicinal products, even to such infinitesimal doses, if their potency demand it, that we may order one-sixtieth of a grain, knowing that by the use of the Springer Torsion Balance scale we can be assured of exact measurements, while our therapeutical knowledge teaches us the duration of its action, and enables us to give it at exact intervals.

And now glancing hurriedly over the intervening period between that to which we have alluded and the present century, we can see really but very little of practical work either in medicines or their methods of administration. We very well know that later medical history is full of names, which, viewed from our distant standpoint, seem like towers of strength. Harvey, Sydenham, Locke, Boerhaave, VonHaller, Cullen, and a host of others cast their shadows down along the ages, but the present power of medicine, and the high status which it has now attained is due almost solely to the enlightenment of this age, and the unceasing labor of the men of our day and generation. By careful and unceasing experiments in materia medica and pharmacy, we have had brought to us hundreds of medicines, with myriads of combinations, and which advanced therapeutics have taught us, have undoubted affinity for individual organs and tissues of the body. Not only do we have medicines which will go directly to, and have their effect upon, the chief organs of the system, such as the liver, the lungs, the heart, the kidneys, and so forth, but patient and careful work has given us remedies which we know act directly upon the cell structure and individual constituents of those organs.

Just as true as we can peer down into the cavernous realms of the brain and with microscopic aid, see its mysterious structure, so true does materia medica hold within her grasp some medicine which will stir a diseased portion into normal working, or calm some excited fibre down to sweetest repose. Just as true as anatomists and physiologists have shown us the minute structure and intricate workings of the kidney, so true has pharmacy prepared for us some medicinal agent which will at once overcome its deflexion from its normal course. And just as true as chemistry has given us the constituents of the great life fluid, so true has Nature, from her boundless resources, poured out the remedy which will enrich her impoverished corpuscles,

and restore them to their natural number and activity, enabling them to carry sustenance to the body and save a human life.

These problems have been worked out within the memory of some one who hears me to-day. Much of it, and by far the most important, has been developed, Mr. President, during the short period of your own professional observation and labor. And although but half a century of years has yet been allotted to the writer of this article, during my lifetime, among the many valuable additions to our department of the science, anæsthetics have been brought into existence; two of the grandest medicines known as cardiants have been discovered; and that grand body of new medicines classed among the antipyretics and hypnotics have made their appearance, and proved their usefulness.

In commending these remedies, I wish to say a few words in reference to the *safety* or the *danger* of chloroform, a subject which has been argued pro and con by every surgeon of note, by all the text books of the land, by every medical journal in every country, and especially by every layman and every country newspaper which supplies a reading public of an area of half a dozen square miles. That its danger has been greatly exaggerated by some of these, and its greater usefulness thereby impeded, I think there can be no doubt. With proper subjects and in careful hands I cannot help but believe that the danger from this well-known anæsthetic is comparatively slight. Its exact percentage of fatal results can probably never be really ascertained, for every death accompanying its use is at once reported and heralded everywhere, while there are unnumbered thousands of cases where it is successfully used, and the knowledge of it never known outside of the humble domicile where it saved some useful life. What is more cheering than the grand results achieved by some of the leading operators of this and other lands? The world-renowned Nussbaum, of Munich, says that he has used it in 40,000 cases and not a death occurred in all that vast number. Dr. Hunter McGuire, the eminent surgeon of Virginia, reports 28,000 administrations, without a single death. Prof. Chisholm, the well-known oculist of my own city, informs me that he has used it in over 15,000 cases, in both military and civil practice, without one unfavorable termination. In my own experience of twenty-eight years of active practice, a part of which was spent in military life, where administrations of chloroform were of almost daily occurrence, I have never yet seen a fatal result, and have seen but two cases where even any alarming symptoms were manifested. Therefore, so valuable an agent as this should not be thrust aside because at some time it has been used without satisfactory results. Deaths have resulted from the powerful aconite,

the gentle opiate and the glistening steel, but we do not condemn them and cease their use. Then let us continue the use of this agent whenever demanded, but always judiciously and cautiously, for if by its administration we can avert a fatal shock to some maimed and unfortunate fellow-citizen; if through its soothing power we can check the deadly spasm in some sweet babe; if by its timely and proper use we may assuage the indescribable pains of some female as she emerges from the dread agony of labor into the sweet joys of maternity; or if to any poor sufferer with his years of pain we may give one moment of relief, we will not have used it in vain.

The two great cardians,—one a depressant, and the other a stimulant,—to which I alluded, are *veratrum* and *strophanthus*. I speak especially concerning the first named because a celebrated writer, in his much-lauded text book, says that "*veratrum viride* is now very little used, hence it is probable that the accounts of its usefulness were very much overdrawn." Now this is not in accord with my judgment and experience. My faith in *veratrum* has borne the test of twenty-five years, and so thoroughly am I imbued with the idea of its usefulness as a cardiac depressant, that in diseases which call for that class of medicines, I regard it as my sheet anchor. In pneumonia and pleurisy it is the one bright star in the firmament of medicine; and if we are to judge the successes of the future by those of the past, it will live as long as diseases will continue to exist and medicines continue to be demanded.

Regarding *strophanthus*, while its action upon the system is so nearly identical with *digitalis*, it is more speedy in its action, and more adapted to heart failure and sudden collapse. Among the scores of cases in which I have used it, I call to mind one in which dissolution seemed almost inevitable. A prominent merchant of Baltimore was so afflicted with cardiac debility that at one of my visits I found him with a pulse of 47, and his respiration reduced to 12 per minute. By a persistent use of the tincture of *strophanthus* he was quickly relieved, and with its continued use alone he was restored to health. His recovery is so far, at least, complete, that he contemplates a tour abroad within the next few weeks, with a journey on foot through Scotland and Ireland. Also with a lady over seventy years of age, with diabetes and heart complications, I found its effects almost marvelous. This new African product is surely a valuable addition to *materia medica*.

Among the newer remedies there are several whose chemical names are long and almost unpronounceable, but whose common names are already familiar to the laity, the introduction and use of which has made a bright page on the chemical, pharmaceutical, and therapeutical lit-

erature of these latter days. Their great prominence and marked usefulness have made them familiar to every one, and antipyrin, acetanilide, phenacetin, and antikamnia are articles of daily prescription by nearly every physician in the land. I must, however, from personal experience, award the meed of praise to sulphonal, that grand quieting agent, which without any appreciable bad results, will on all occasions bring about that perfect rest which every one requires; that remedy which gently soothes to sweetest slumber the almost heart-broken babe; which calms and stills to rest the tired and worried brain of the ambitious merchant or professional man; and which drives away, for the time, all care and sorrow from the aged and infirm.

In conclusion, if in my research and my own personal experience, I have proved the salutary influence of some of these grand remedies, and shown the present exalted status of *materia medica* and therapeutics which this paper is intended to prove, or have said aught that will have a tendency to further elevate our profession, or relieve a sufferer, my purpose has been accomplished. And if, in its preparation, I have advanced a single thought which has won the commendation of some physician here, or if in its rendition I have uttered a single sentence which has fallen acceptably upon the ear of any one present, I am perfectly content.

THE WORKING BULLETIN SYSTEM, NATIONAL PHARMACOLOGICAL ASSOCIATION, NATIONAL LABORATORY,

AND A PROPOSED INVESTIGATION OF THE MATERIA MEDICA OF THE WORLD UNDER THE AUSPICES OF THE GOVERNMENT OF THE UNITED STATES.

Read in the Section of Materia Medica and Pharmacy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY F. E. STEWART, M.D., PH. G.,
OF WILMINGTON, DEL.

Materia medica is the name given to the collection of substances used in medicine; Pharmacy is the science of preparing medicine; Therapeutics is the science of applying medicine to the curing of disease. These branches, related and mutually dependent, are classified under the general head Pharmacology, or the science of drugs.

"Science professes to teach what is already known or may be learned in the forms of exact observation, precise definition, fixed terminology, classified arrangement and rational explanation." This science, therefore, embraces in classified forms *Materia Medica*, or the substance employed in medicine; Pharmacy, or the preparation of medicine; and Therapeutics, or the application of medicine to the cure of disease.

Art is the application of science to practical purposes.

Physicians practice the art of therapeutics, or, in other words, put in practical application the knowledge of applying medicine. Pharmacists practice the art of pharmacy, or, in other words, put in practical application the science of preparing medicine. Both in their respective fields, therefore, are practicing arts of medical science.

Physicians and pharmacists are mutually dependent, for medicine cannot be applied until it is prepared, neither is there any use for preparing it except it may be applied.

The practice of therapeutics should be confined to those who are educated in the knowledge of disease and its treatment; and the practice of pharmacy should be limited to those educated in the nature of drugs and their preparations.

The practice of the professions of medicine and pharmacy is being diverted from its legitimate channel and is undergoing rapid absorption by commercial houses. The competition between these houses and the professions is disastrous, because, while the former is permitted to use various well-known business methods to bring themselves into contact with the public, and create a demand for their commodities, the latter, and especially the medical profession, is forbidden to take advantage of these methods. It is, therefore, a competition of capital and business ability on the one side, and on the other, the more exact methods of science in the hands of professional men whose entire service must of necessity be limited to a very different field. The trade in medicines has the most powerful of all methods at its command, viz.: advertising. The medical profession is denied this method of creating a demand. Furthermore, the advertising system is purposely misleading, and claims are made in regard to the curative nature of drugs entirely unwarranted by facts; but the medical profession, standing faithfully on the side of truth, does not possess an equal chance of financial success. Barnum has truly said that the public prefers to be humbugged, and medical humbuggery is such a money-making business in this country that the professions of medicine and pharmacy stand a poor show in competition with it.

The purpose of my paper is to consider some of the methods whereby the practice of pharmacy and medicine may be returned to their legitimate channels.

First, the commercial prestige of these so-called great patent medicine houses is due in a great measure to what is known as the Proprietary Medicine System. By this system they are enabled to create lasting and secret, or semi-secret, medical monopolies, become immensely wealthy, and exert the most powerful influence over all medical legislation. Medicinal prepara-

tions are put on the market with a large margin of profit, which enables the manufacturers to create an immense demand by misleading advertisements. As they do not fear competition, it is comparatively safe to sink a hundred thousand dollars in marketing one of these articles, for the return is a large one in the long run, and the market once gained, can be held indefinitely against all newcomers. I am aware of one instance where a medicinal preparation of the kind was placed on the market at \$90 a gross, and cost only \$12 a gross to manufacture it. The enormous profit of \$78 a gross on a business that figured up into the millions permitted the manufacturer to expend an enormous amount of money in advertising. The original formula was that of a weak infusion, and taken from Gross's Surgery, and the article was advertised as a "Highly Concentrated Compound Fluid Extract."

The first thing to put out of the way, therefore, in adopting any method of reform, is the proprietary medicine scheme. Instead of endeavoring to do this, however, the medical profession during the last fifteen years has made the system comparatively respectable by adopting a large number of so-called copyrighted and trademarked pharmaceuticals and new chemical preparations.

The Code of Ethics of the American Medical Association clearly condemns the prescribing of medicines which are restrained from general use by any or all of these methods of monopoly. At the same time, while this is true, a large number of the members of the Association have so far forgotten their obligations that they use the articles referred to very extensively in practice. This situation of affairs is very demoralizing, both to the profession and to the public; and the prescribing of such preparations is an act of great injustice to the pharmaceutical profession of this country, because it forces the apothecary into all manner of irregularities, so-called, to obtain a livelihood.

But there are even greater reasons why the medical profession should seriously consider the present tendency of the times in this department of medicine, for the proprietary medicine system is a continual menace to medical science and practice.

In the first place, there is entirely too much misunderstanding in the minds of medical men in regard to the nature of the patent privilege. The Constitution of the United States gives Congress the power to promote progress in science and useful arts, by securing the authors and inventors, for limited times, the exclusive use of their respective writings and discoveries. On this provision of the Constitution is founded our patent and copyright laws, but not our trademark laws. A copyright secures to authors for limited times the exclusive use of their writings,

while the patent law secures to inventors for limited times the exclusive use of their inventions. The copyright and the patent are precisely the same thing, only one applies to authors, and the other to inventors.

A trade-mark, however, as applied to the arts, is merely a commercial signature to distinguish the goods manufactured by one man from those manufactured by another; in other words, it is employed to distinguish one brand from another brand of the same article of commerce. But suppose for a moment each art to be a monopoly, of what possible use would be the trade-mark? An invention of course must be provided with a name by which it may be recognized and dealt in. By the proprietary method this name is registered as a trade-mark, and a monopoly is secured perpetual in character. Rights are thus obtained of a nature far more restrictive than those permitted by the patent. Where does the authority come from which permits inventors to thus secure for an unlimited time the exclusive use of their inventions?

It certainly does not come from the patent law.

A patent is a contract between the inventor and the government, representing the public at large, by the terms of which the inventor is granted the exclusive use of his invention for a limited time in exchange for the publication of a full knowledge thereof, whereby the public may manufacture the invention when the patent expires. Where does the authority come from which defeats the very end for which the patent law was devised?

At least one learned judge has said: "When an article is made that was theretofore unknown, it must be christened with a name by which it can be recognized and dealt in, and the name thus given it becomes public property, and all who deal in the article have a right to designate it by the name by which alone it is recognizable."

About a year ago I read a paper before the House Committee on Patents of the United States Congress, taking the same view of the case; and while the committee said that it could not constitute itself as an interpreter of the law, it was the sense of those present, that no such monopoly was ever contemplated by the trade-mark law. In a subsequent conversation with His Excellency, Mr. Benjamin Harrison, President of the United States, he said that the Supreme Court was the supreme interpreter of the law; and, on a point where there was so much dispute, a test case would probably have to be presented to it before the matter could be finally settled.

But a very similar point was long ago settled by the Supreme Court in relation to copyright, and I do not see why the decision does not apply with equal force to the subject under consideration. "In 1834 was contested in the Supreme

Court of the United States the same question which had been so elaborately argued in the English case of *Millar vs. Taylor*, decided by the Court of King's Bench in 1769, and finally settled by the House of Lords five years later, in *Donaldson vs. Becket*, viz.: whether copyright in published works exists by the common law, and is therefore of unlimited duration, or is created by and wholly governed by statute. The Supreme Court, following the authority of the House of Lords, held that there was no copyright after publication, except for the limited time given by the statute."

It has been advocated that the same articles be introduced under new names, but this is objectionable, because the old names have already secured recognition in scientific literature to a greater or less extent; and confusion would result if such a plan is adopted. This is especially true if the suggestion once made should be put in force, whereby each manufacturer should have a trade mark name for the same article. Imagine the load of synonyms that would accumulate in a few hundred years. Furthermore, the public has a perfect right to manufacture any article that is not patented, and not until the new name thus introduced becomes equally known to the public, has another manufacturer an equal chance with the inventor to manufacture an article to which he has an equal right. Finally, there is a right way and a wrong way for the medical profession to look at this question of trade mark names which is so seriously injuring medical nomenclature. For the profession to adopt the wrong way, or dodge the issue, is not only to show cowardice, but to tacitly endorse or sanction the unscientific scheme of the proprietary trade.

Next, I wish to present to your consideration this point: While there may not be any apparent difference between the practice of a professional man and a tradesman, the true difference is plain enough when motives are considered. A tradesman practices his vocation for the sole purpose of making money. If he takes any interest whatever in scientific matters, or in the good of his fellow-tradesman, this is incidental. A professional man, on the contrary, is actuated by a very different motive. He practices his vocation to benefit science, elevate his profession, and serve the cause of suffering humanity; and money making is incidental. It is the faith of the public in the altruistic nature of medical practice that gives confidence under the many trying circumstances attending sickness and death. What person would call in a physician whose reputation was that of one who practices medicine with the primary object of money making? Such a man's services would be rendered in proportion to the pay. The poor have just as good right to the very best services of the best physicians as

the rich, and this principle is recognized everywhere.

Again, the standing of a commercial house is founded upon its business prestige; but the standing of a physician is founded upon the value of his services to medical science, to his profession, and to the cause of suffering humanity.

Now I claim that pharmacy, being a branch of medical science and art, should be practiced as a profession, not as a trade; and the standing of a pharmacist should be founded, not on his commercial success, but on his contributions to medical science, and the value of his services to the profession and to the public.

If the line were drawn by the medical profession between pharmacy as a profession and pharmacy as a trade, there are plenty who would step over this line to the side of scientific medicine; and the class of pharmacists and manufacturing houses thus created could be trusted to take care of the scientific and professional interests of this important department of medicine.

For more than ten years I have been preaching this doctrine with more or less success. On the side of professional and scientific pharmacy it gives me great pleasure to see such pharmacists as Hynson and Wescott, of Baltimore, Frank Morgan of Philadelphia, and such manufacturing houses as Parke, Davis & Co., of Detroit, and Dr. E. R. Squibb, of Brooklyn, and such wholesale drug concerns as Gilpin, Langdon & Co., of Baltimore, and several others. This is very encouraging, but it is discouraging to meet with such experiences as the following:

Some time ago I had a talk on the subject of pharmacy with a well known college president, Prof. M.D., and L.L.D., who said he considered that the pharmacists occupied the same position to him as his cook; and he did not care what either of them did so long as one furnished him with properly cooked food, and the other one with properly prepared drugs.

Again, a large pharmaceutical house, acting with a purely professional and scientific motive, spent years of costly endeavor in the investigation of standards for vegetable drugs and galenical preparations. As the result of these investigations it introduced a class of standardized preparations known as "Normal Liquids," and gave the entire work to science by presenting it to the committee for revising the United States Pharmacopœia. By so doing it practiced pharmacy as a profession; and deserves just as much professional and scientific credit and recognition as any physician in the land. And yet it has been openly advocated that while the work itself is of the greatest value to science, and to the profession, and should therefore be accepted because greatly needed, the name normal liquids should not be adopted because it would give this house great commercial prestige. As well might you

say to Dr. Koch, "Your work on the subject of bacteria as a cause of disease is excellent, and should be accepted, because of great benefit to science and the cause of suffering humanity; but while we accept your publications they must be contributed in an anonymous manner, because if any body should happen to find out the author of such valuable work it might give you great prestige as a practicing physician."

Finally, the question of standardizing medicines is one that merits consideration. "As laws are at present constituted a poison can be legally sold as such in most States only with a glaring label of warning, and after double or triple forms of registration by a competent pharmacist. Put it up as a patent medicine, decorated with a seductive title, and a rainbow wrapper, and at once it is beyond the restraints of regulation, and may be sold by street-hawkers, slaughter shops, anybody and everybody, without let or hindrance." Where is the consistency that discriminates by such strange partiality in favor of charlatanism, and does such injustice to intelligent pharmacists. I am informed that in France, the law is so strict that no one except regular physicians and first class pharmacists are allowed to put up medicines and sell them to the public. Laws should also be passed in this country restraining anyone from manufacturing and selling medicinal preparations without being properly qualified by education and experience.

Again, I am told that in France before anyone is allowed to market an article he is asked by the government for a copy of his formula and a sample of his preparation. Both are handed to a government analyst who makes a careful analysis of the article, and if it proves in any way below the standard prescribed in the formula it is suppressed. If it passes this examination it is directed by the Academy to be used in hospitals where patients suffering from the peculiar disease for which it is recommended are received; and there it is thoroughly tested for several weeks and the effects duly noted. If it proves effective then its compounder is allowed to manufacture and sell it, after the formula has been duly published in some standard work.

I have already referred to the interesting question now exciting so much interest in medical circles, viz., the standardization of vegetable drugs and galenical preparations. This is an excellent move so far as it goes, and I believe with my esteemed friend, Prof. Remington, that every important drug and important preparation should be standardized whenever a process can be devised which is practical, readily applied, and which is applicable to the needs of the pharmaceutical and medical professions as a whole. But I go still further than this and insist that every medicinal preparation introduced to the public should have some recognized standard, and the manufacture should

be held up to that standard by imposing severe penalties for adulteration. A national law to prevent the transit of adulterated products from one State to another, and State laws to control the manufactures in each State would probably be necessary.

To sum up the entire matter, therefore, I again assert that the manufacture and sale of medicine and the treatment of the sick is being diverted from its legitimate channel, which consists of the physician's prescription compounded by the educated apothecary, and directed into the hands of uneducated merchants ignorant alike of disease or its treatment. Both physicians and pharmacists are suffering much through this unfair competition, and many of the irregularities in the relations between the two professions can be traced to this cause. Science is hindered and scientific nomenclature seriously threatened; much of modern pharmacy has no place in literature whatever, and partial information only can be found in the advertising pages of medical and pharmaceutical periodicals which are destroyed at the end of the year. Pharmacopœias and text-books, dependent as they are upon this knowledge, are suffering the consequence; while students in our medical and pharmaceutical colleges cannot be instructed in the composition and use of many articles which they will afterwards use in their practice; physicians hesitate about writing articles concerning preparations employed by them in treating the sick, for fear they will be charged with dishonorable motives; journals object to receiving such reports, either because they are afraid that readers will think admittance to their columns has been gained through bribery, or because they prefer that all such mention shall go through their advertising columns and be well paid for. And finally, there is no protection to the public in this connection by either the medical, secular, or religious press; for the entire press of the country is so thoroughly subsidized by advertisers that there are but few publications sufficiently independent to say anything on a subject which may injure their advertising patronage. Taking all of these facts into consideration, is there not sufficient reason for alarm?

How then can this great evil be remedied? My suggestions are as follows:

1. I would suggest that an association be formed with a membership of both physicians and pharmacists to be known as the American Pharmacological Association.

2. For the purpose of ascertaining the true value of drugs and compounds now in use, as well as all new introductions in the future, I would suggest that a national laboratory be established to test drugs and medicinal preparations from all points of view, and that this laboratory be manned by physicians and chemists selected from the medical department of the Army, Navy, and Marine Hospital Service.

3. I would suggest that this national society, with the aid of the laboratory referred to, take up an investigation of the *materia medica* of the world to ascertain what substances are used by various nations as medicine—this to include both civilized and savage people. Such an investigation would be of immense profit not only to medical science, but such sciences as botany, anthropology, etc., etc., and could be carried out without great expense by the medical men in the employ of the government, who now have very little to do.

4. I would suggest the adoption of some such plan as that in use by France, whereby the manufacture and sale of drugs and medicinal preparations shall be limited to those qualified by education and training for this responsible vocation; that nothing shall be introduced as a medicine unless first submitted to the national laboratory and tested, first on animals if possible, and then by the hospital service throughout the country, after the true formula has been published, and the claims made by the introducer shall have been properly authenticated. It is better to experiment with patients in the hospital under proper restrictions than to leave things as they are at present, for the patent medicine trade are now experimenting on the public at large without any restrictions whatever. To carry on this work, "Working Bulletin," containing all obtainable information concerning the drug or preparation, should be extensively circulated to physicians connected with the hospitals throughout the country. And a monthly journal should be published as the organ of the National Pharmacological Society. Scientific expeditions should be sent out to explore uninvestigated parts of the world, hoping to discover valuable medicinal plants. Botanical gardens should be erected in connection with the work to further knowledge of the cultivation of medicinal plants.

5. Finally, I would insist that a patent should never be allowed for a medicine unless it be first proved to be a new and useful invention as a therapeutic agent by the tests that I have indicated. And then, if it be deemed wise on the part of the Government to grant a medical inventor the exclusive use of his invention for a limited time, I don't know as there is any objection to it.

This plan which I have suggested for investigating the *materia medica* of the world, is not so visionary as it might appear without due consideration. The working bulletin system, the hospital plan, the monthly journal as an organ of the work, the scientific investigation of the *materia medica* of various unexplored regions such as the valley of the Amazon, the interior of the Fiji Islands, and the Islands of Jamaica, are things that already exist, and have been carried out; and the journal I refer to, the *Therapeutic Ga-*

zette, is universally acknowledged by all authorities both in this country and in Europe to be the leading journal in therapeutics in the English language. So far as the working bulletin system is concerned, if the profession would do its share the bulletin would become far more valuable than they are at present, though they receive compliments from every quarter. If so much can be accomplished as has already been done by the enterprise and liberality of a private corporation, Messrs. Parke, Davis & Co., of Detroit, how much more might be accomplished if it was taken up with all the resources of the United States Government. Under proper governmental auspices the work would be raised to a level where it would be no longer hindered by the attacks of business competitors, who do not hesitate to ascribe the most selfish motives to every move that has been made. And it would be no longer crippled by the constant attacks of the proprietary medicine trade who greatly fear any plan calculated to destroy their monopolies and prick their bubbles.

The following comments, received from well known authorities, well illustrate the favor with which the plans suggested in this paper have been received.

Prof. Spencer F. Baird, Secretary of the Smithsonian Institution, when I submitted the plan to him originally, said that I might tell my friends that in his opinion it was one of the most important plans ever submitted to the Institution.

Prof. H. G. Beyer, Curator of the National Museum, in a letter written October 20th, 1885, says: "I most sincerely sympathize with you in your plans of trying to organize the association you speak of, and you may depend on my hearty coöperation in the matter, so far as I am able to assist you. I think your conception of establishing a Bureau of Department of Pharmacology under the Government a grand one, and no doubt one that ought to be carried out. We have here all sorts of scientific Bureaus, and it seems to me not one which is calculated to be of such immediate benefit to mankind as a Department of Pharmacology would be to the American people, not to speak of the immense scientific value it would be to medicine and pharmacy. I, for one, should certainly hail the inauguration of such an institution with great delight. It is exactly what I have been having in mind for the last year and a half."

THE eighth annual meeting of the New York State Medical Association will be held Wednesday, Thursday and Friday, October 28, 29 and 30, 1891, at the Mott Memorial Hall, 64 Madison avenue, near Twenty-seventh street, New York City. Sixty papers appear on the programme.

THE FUTURE CHEMIST.

Read in the Section of Materia Medica and Pharmacy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY CHAS. T. P. FENNEL, M.D.,
OF CINCINNATI, O.

When I was invited to undertake the honorable task of presenting a paper on this memorable occasion, the beginning of a new era for physicians and pharmacists, I felt a hesitancy in accepting, being cognizant of my unfitness to select and consider a subject worthy of, and of equal importance to, both professions.

The beginning of a new era! American medicine has extended her arms and taken unto herself American pharmacy. The vocabulary of the English language is inadequate to express the gratitude due to the American Medical Association. Henceforth, the two professions go hand in hand; and if we are only content to await the harvest of the seed that has been sown, our granaries will, in good time, be filled with golden grain.

All nations reverence antiquity. Historians have ever been ambitious of tracing back their subjects to the most remote antiquity. Writers on medicine and allied sciences have not manifested less eagerness to discover the origin of their art, but in every attempt to thread the stream to its source, were soon lost in the wilds of conjecture or the regions of fable; indeed, it is very unlikely that we should be able, by the most indefatigable research, to approach the period when remedies were first applied for the alleviation of bodily suffering, or to discover any country, no matter what its state of civilization might be, in which its native inhabitants were destitute of medical resources. Looking back to my early days, when I learned the rudiments of practical chemistry in the laboratory of a pharmacist, I can fully realize and appreciate the gradual but wonderful advancement made in the last twenty-five years.

Retrospection and introspection. What lessons of practical wisdom do they unfold? What reminiscences may they call forth, and what beacons for future guidance reveal? Epochs in the life of man, when he feels how little he knows, and how much of Nature's secrets are still to be unraveled.

The close of every decennial marks an epoch in the history of American pharmacy, and it is well to look backward for a moment upon the past, and see what has been accomplished for the betterment of American pharmacy.

In the progress of civilization, pharmacy has kept abreast of the other natural sciences, which is substantiated by the improvement in each succeeding pharmacopœia. American pharmacy has completed another period of time in its history. A new pharmacopœia will be upon us before long,

and, judging from the preliminary labors, will be a credit to American science.

Comparison alone will forcibly impress one with the absurdity of some, and the total inactivity of many preparations.

Impelled by curiosity and a desire for information, one seeks to inquire for the reason why some substances, held at one period in the highest esteem, should have fallen into total neglect; why others, of apparent insignificance, should have held their position so steadily, and again, why others which have been denounced as inert and worthless, should have been raised into special favor once more.

Superstition and speculation have been laid aside for fact and demonstration. Medicine and pharmacy are no longer in the category of a craft or a delusion, but sciences established upon solid and definite bases.

The advances made in the science of medicine are, in a great measure, due to the discoveries in chemistry by the early pharmacists, and who, in reality, are the founders of modern chemistry. In tracing the history of chemistry, not in the sense of the science of to-day, from its earliest period, we find that its progress to its present advanced state has been exceedingly slow. Chemistry is virtually as old as the history of mankind—a rash assertion, perhaps, but one which may be defended by the statement that vinegar is mentioned in the Old Testament, and is in all probability the oldest acid known.

To prolong life was a problem that engaged the attention of mankind from the earliest ages. It was not until the rise of alchemy, however, that the search of an elixir vitæ as a scientific possibility engaged thinking men. The science of alchemy can be traced back to the third century, though efforts have been made to trace the origin, by tradition, to Egypt. Geber and the great physicians of Arabia were the representatives of alchemy; the time constituting the second period of the history of chemistry.

The next period is known as the time of medical chemistry.

The results obtained were the work of physicians, among whom Paracelsus stands preëminent. All the investigations were made in reference to the healthy and diseased condition of the human body, and the consideration of remedies that would restore the equilibrium displaced by disease. There was a long time between Geber, Paracelsus and Priestly. The birth of modern chemistry is accredited to the eighteenth century, Priestly and Lavoisier dealing the death-blow to alchemy and iatro chemistry. During these periods of time, more or less attentive observations had been made on the properties of natural bodies, various theories had been formed, and different ideas had been entertained concerning the nature of those bodies. The greater proportion

of these were vague and unwarrantable, and in many instances positively absurd.

The fate of these cautioned the judicious part of the inquisitive world of the necessity of substituting experiment and strict mathematical reasoning for the suggestions of the imagination.

This rational reform, which commenced with the seventeenth century, was productive of a vast number of useful discoveries.

We may well quote Sylvester Baxter: "As in a journey from one climatic zone to another, we have been slowly leading up to new conditions; but the changes, like the movements of a clock's hour hand, are so gradual as to be scarcely perceptible. Suddenly we are aware that circumstances have become quite different from those we remember well back in our way."

Medicine, chemistry and pharmacy are not independent sciences, but dependent upon each other. Every particle of matter in the cosmos bears some sort of relation to every other particle of matter in the cosmos. The advances made in one direction, will naturally be available for further progress in another direction.

Scheele, the Swedish chemist, enriched the science with many discoveries, and contributed much to the progress of practical chemistry.

These discoveries gave new impulse to the study of medicine. In fact, no progress could have been made in medicine without the key of Priestly's "Oxygen," unlocking the secrets of nature.

The advancement of medicine, more so than that of chemistry and pharmacy, has been continually arrested, and often entirely subverted, by the caprices, prejudices, superstitions and knavery of mankind.

American medicine and pharmacy are, to some extent, still the sufferers from the same causes. But we are leaving the oft trodden path of history, and must go back in time to secure the evidences which make the sciences of to day. Apparently as marvelous as the discovery of the elixir vitæ or the philosopher's stone, were the discoveries by Sir Isaac Newton in 1675. Amongst all the discoveries of modern science, none has deservedly attracted more attention than the results of the application of spectrum analysis to chemistry.

What have not the discoveries of Newton done for medicine?

The application of the principles involved in his discoveries increased the technique of the microscope. Leuwenhoek may justly be called the father of scientific microscopy, and as having set a most admirable example of scientific method in the prosecution of biological research. These methodical investigations, and the realization of results in the domain of the invisible world, have progressed with such wonderful rapidity as to be almost beyond belief.

We have reached the dawn of a new era in medicine and chemistry.

Observations have shown that in the decompositions of all organic matter, and in disease, microorganisms will result.

All animal and plant life consists of a mass of complex, unstable chemical substances, capable of being oxidized and reduced to simple, more stable substances, with the setting free of energy. This continual setting free of energy constitutes a drain which must be met by constantly renewed supplies, which we call food. When animal or plant life is supplied with appropriate food material, and exposed to favorable external conditions, we perceive continual changes of construction and destruction.

The processes of decomposition, by which relatively simple substances are produced from relatively complex ones, form the issue of to-day.

The most active agents in producing chemical changes are bodies which are termed "ferments," and the process fermentation and putrefaction. Originally, the term "fermentation" implied the effervescence and evolution of carbonic acid gas; but the accepted definition of to-day implies peculiar changes to which complex organic substances are liable. Putrefaction is virtually a process of fermentation, and only differentiated from it by the products of decomposition being of a disagreeable and obnoxious odor. The ferments are distinguished as organized and unorganized. But little is known of their chemical composition, and much less, in fact, nothing, is known of the properties upon which their characteristic action depends. As examples of organized ferments, we have yeast and bacteria. The former we know to be a very complex mixture of fats, cellulose, albuminoid nitrogen and salts; the salts consisting of phosphate of magnesium, potassium and calcium; but of its constitutional structure we know nothing, and much less upon what action depends.

To the casual observer the souring of wine or milk, the spoiling of all kinds of food products, might appear spontaneous, without the application of any substance from without.

The chemist is well aware that the changes are non spontaneous, and hence must be produced by substances or reagents, although these may not enter as a factor in the mathematical chemical explanation. These are the peculiar changes to which complex organic substances are liable, and many theories have been advanced to explain these processes.

Experience and observation have proven that fermentation always takes place in the presence of water, under varying temperatures and in contact with some specific ferment. Although apparently the ferment does not contribute to the final product, its presence is essential. Berzelius called it catalytic action; that is, by contact.

Stahl claimed that the preëxisting molecular motion was disturbed by the molecules of the ferment, and caused the formation of new compounds, in which the molecular motion was equalized by the disturbing element.

Liebig claimed that the unstability of albuminoid substances in the presence of water was so great, that the least oxidation would disturb the chemical equilibrium to such an extent as to rearrange the atoms to form new compounds of greater stability.

So far, the question of process had been considered from a purely chemical standpoint.

Schwann, Cagniard and Latour examined the so-called yeast ferment under the microscope, and found cells similar in character to vegetable cells, and that these, under proper conditions, increase and multiply.

They naturally concluded that yeast is a species of plant, and that the life of this plant produced the change.

The theory advanced was readily taken up by others, amongst whom Helmholtz, Mitscherlich, Hoffmann, Schroder and Dusch did admirable work, but not one of them made any really progressive move. It remained for Pasteur to repeat all known experiments and verify them, but his renown was established in cultivating pure growths of each species, and examining each for its chemical action.

Ferments have been classified according to the nature of the chemical changes which they induce; that is, oxidative and splitting fermentation. A few coming under the head of the latter may be produced by purely chemical means.

The conversion of cane sugar into dextrose and levulose can be accomplished by purely chemical means, by the use of strong mineral acid, especially sulphuric acid.

Organized ferments, as the yeast plant, cannot ferment cane sugar directly, while it can induce the alcoholic fermentation in the glucoses. In the fermentation of cane sugar by the yeast plant, the same splitting up of the atoms of sugar must take place as is accomplished by chemical means, in order to induce alcoholic fermentation. This process, known as the inverting of sugar, is produced by a soluble ferment which accompanies, and is probably produced by, the yeast plant itself.

Fermentation is no doubt a nutritive process for the ferment-producing organisms, with its consequences.

In like manner, the butyric fermentation follows the lactic fermentation. Changes are produced in the albuminous constituents of milk by the lactic ferment, which is conducive to the health and growth of the butyric ferment.

The proteids of milk must consist of more than the single complex substance which we call casein, for its precipitation with neutral salts, acetic

acid or coagulation, is not accompanied with uniform results. I feel satisfied that the day is not far distant when it will be shown that the so-called casein consists of a soluble and an insoluble part, possessing different properties, and exerting influences characteristic of each.

Analyses of milk, preserved and condensed by recognized authorities, are so at variance with each other, that it is impossible for the chemist to decide upon a standard.

The conversion of starch into dextrine and dextrose, milk sugar into saccharine bodies, one crystallizable, the other not; decomposition of glucosides, are all possibilities of the chemist.

The agent used to accomplish the desired result, and taking the place of the ferment, does not enter into the chemical equation, any more so than the ferment.

The fermentation produced by the unorganized ferments, diastase, emulsin, myrosin and erythrozym, cannot, by chemical means, be produced with like results.

The digestion of the food is nothing more than a physiological fermentation which food undergoes previous to its absorption.

According to Charles and Landois, the gastric fermentations of proteids end with the formation of peptones, soluble and diffusible.

The pancreatic fermentation is more complicated, the results of decomposition being peptones, leucine, tyrosin, aspartic acid and glycocholl. As a subsequent result, we find that the medium is now conducive to the growth of microorganisms, the products of their process of nutrition being indol, scatol, phenol, fatty acids, hydrogen, carbonic acid gas, dihydrogen sulphide, ammonia, and finally ptomaines.

An artificial digestion of albuminoids is partially accomplished by dilute hydrochloric acid, but the resultant product does not deport itself as a peptone. The products of pancreatic fermentation have never, so far as we have knowledge, been obtained by chemical means, although it has been found, by experiment, that artificial pancreatic digestion readily advances to the putrefactive stage, with the formation of like products.

In all the various forms of fermentation, whether by organized or unorganized ferments, the processes are in the nature of a progression, the evolution is gradual, but each stage is dependent upon the preceding one. The process may be interrupted, but it never can become retrogressive. The ferment may be constrained to live under abnormal conditions, but it soon becomes exhausted, unless revived by artificial means. Under such conditions, it is not surprising that standards may appear arbitrary and misleading.

Aside from the data furnished by chemical analysis, other factors must be introduced, the source and nature of the source, and the consid-

eration of the influences, light, air and heat.

It is therefore necessary, to obtain conclusive results, to take cognizance of the inevitable decay, whether a process of fermentation or putrefaction, influenced by living organisms, or a chemical decomposition with the formation of compounds conducive to the growth and development of living microorganisms.

The scientific, as well as the pharmaceutical chemist, can no longer stand alone, he must call to his aid the biologist; and where could he have better opportunities to find him than among the medical profession.

The results of their combined efforts will furnish indisputable facts, and be based upon biological-chemical data as solid as the rock of ages.

The American Medical Association has indeed performed a noble act, in offering the opportunity for developing a higher culture and a more comprehensive education.

PHARMACY FOR MEDICAL MEN.

Read in the Section on Materia Medica and Pharmacy at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY P. W. BEDFORD, M. D.,
OF NEW YORK.

The education of the medical student of the past as well as of to-day is neglected in one of its most interesting and necessary departments, that of pharmacy. It is not necessary to ask any one of this assemblage as to the amount of actual experience he has had in the handling or manipulation of the drugs he prescribes, or whether he has ever prepared the prescriptions he directs for his patients. There are doubtless some who have had such education or experience, but they are the exceptional cases. Those that have had the previous training of the pharmacist or who may, during their student life or at some subsequent opportunity, have given attention to the subject of pharmaceutical manipulation, invariably attest its great advantage to them in their future professional success, both in the curative as well as the educational experience. It has come under my own observation in numerous instances that the student of pharmacy, who at a later period becomes a student of medicine, is apt to be a leader in the profession of the healing art.

My object in the very brief paper that I bring to your notice, is to urge that in the curriculum of the medical student there should be some place assigned for such an amount of pharmaceutical instruction as would enable him to know, by practical work as well as lectures, the things that specially interest him as a provider of the "ways and means" of restoring health to the ailing and distressed. I believe that it is conceded that even yet there are many medical grad-

uates who in their practice find it necessary to carry to their patients in remote places the remedies as well as the advice, and if this be so the medical colleges should provide methods of instruction in this department. There is not the need that either of the professions should usurp the border-land which divides the one into a class whose function is to diagnose the difficulty and devise a method of relief or cure, and the other to carry into effect the suggestion of the former observer. It is wise that each, however, should have the knowledge which goes farther than simply to have memorized facts or statements made by the professor to whom he listened, and that as "practice makes perfect," so there should be an earnest effort made to give the medical student a practical acquaintance with the drugs, chemicals and preparations he is in the future to depend on for success in his combat with disease. The department of "materia medica" should, like the title of the section under whose beneficent wing we gather today, have a permanent suffix, the additional title, "and pharmacy," or it would be still better to dignify the college as well as the position by adding to the professorial ranks a special department and a "professor of pharmacy."

The work and teachings need not be, in fact, should not be, the same as to a class of pharmacists; rather would it be a series of practical demonstrations to a class of twenty or thirty students at a time, and each be required to go through a regular graded course of practical work following the oral instruction or lecture given.

With such a brief but comprehensive plan of instruction for medical students in the future, we will have an improvement in the merit and appearance of prescriptions as they are dispensed, the products are more likely to represent the advanced knowledge of the times, and the prescriber be more in touch with the pharmacist in the needs of efficient yet reliable medication. For the practitioner of to-day we would urge that a little more thought be bestowed on the "prescription," that it be a trifle plainer in its chirography than the average sample of what the busy practitioner sends out as his request for remedies, and that the combination be so arranged that it is free from those incompatibilities which make the product one which is unsightly to the patient, striving to please the eye and palate while retaining efficiency unimpaired. The outline for such instruction which is appended to this paper is merely a suggestive one, but which may form a suitable basis to be varied as may best suit the convenience and arrangement of instructor and class. It is, however, urged that there appears to be but little work of this kind as yet attempted in medical colleges, so far as appears from their printed prospectus, and it is believed

to be one of the important sections which should be impressed on the medical student.

THE PHARMACY OF CRUDE DRUGS AND THEIR PREPARATIONS. CLASSIFICATION AS TO THEIR PHYSICAL CHARACTERISTICS,
ROOTS, BARKS, LEAVES, FLOWERS,
FRUIT, SEED, GUM, RESIN,
GUM RESIN, OLEORESINS, BALSAMS.

Of the 261 articles from the vegetable kingdom which are official in the U. S. P., 1880, all are either under the above classification or are products of the same. For the therapeutic study of these articles as remedies they might be re-classified in appropriate tables for reference and study under the title of the remedial action they exert, as anthelmintics, antipyretics, astringents, cathartics, diuretics, nervines, etc. For their pharmaceutical consideration they may be best studied by taking the crude drugs in the order given above, noting the methods of reducing them to a condition in which they can be made serviceable for medication, as also yielding such preparations as the U. S. P. calls for as obtained from them.

This will bring in the processes of drying, contusion, grinding, sifting, preparing graded powders, and permit of showing methods of detecting adulterations and sophistications of the drugs in the whole and powdered condition.

From the drugs may be prepared at the several succeeding lessons as practice work:

Infusions: The official and other non-official.

Decoctions: Of various drugs.

Tinctures: Aconite, benzoin, kino, cinchona co., guaiac, nux vomica, opium, squill.

Syrups: Tar, wild cherry, rhubarb, squill, senega, tolu.

Fluid extracts: Gentian, ergot, cotton root, ipecac, licorice, hyoscyamus, senna.

Extracts: Indian hemp, gentian, hyoscyamus, nux vomica, opium.

Solutions: Mucilage, acacia.

Expressed oil: Cotton seed, castor oil.

Volatile oil: Clove, cubeb, cinnamon, copaiba.

Distilled waters: Water, (unofficial) from cinnamon, fennel.

Resins: Jalap, podophyllum.

Oleoresins: Cubeb, ginger.

Mixture: Ammoniac, almond, asocetida, emulsion cod liver oil, emulsion turpentine.

Pills: Aloes, cathartic comp., rhubarb comp., nitrate silver, permanganate potassium.

Powders: Ipecac and opium, jalap compound.

Ointments: Belladonna, gall, veratrine, suppositories.

Alkaloids: Quinine, morphine.

Glucoside: Santonin, preparation of various prescriptions, incompatibilities pointed out.

Following the guide of the U. S. P., the dis-

pensatories or Remington's practice of pharmacy, this outline will bring into service nearly all the manipulations that appertain to preparing and dispensing medicines except purely chemical work, and could well utilize two hours each of fully twenty gatherings.

THE PHARMACY OF MEDICAL PREPARATIONS.

Laboratory work should be an absolute requirement for each medical student, and the explanatory lecture of half an hour should be followed by two hours practice by the class. This course should begin with practical work in weights, measures, and specific gravity, and no one should be excused from this until he thoroughly comprehends and satisfactorily demonstrates the principles involved, both orally and practically. The relations between the Centigrade and Fahrenheit scales should be equally impressed. The effects of solvents on chemicals should be studied, then heat in its various applications, for each operation selecting some process which will make some pharmacopœial article. Evaporation of solutions furnishes the methods of crystallization, granulation and exsiccation. Sublimation will give opportunity to study the products of arsenic, mercury, sulphur, and other volatile bodies. Distillation will enable many of the acids to be produced and experimented with for identification and purity, and heat evolves most of the gaseous bodies so that they may be studied.

Precipitation is a means of producing many chemical bodies, and this process is capable of illustrating interesting facts which also apply to other branches of pharmacy than chemicals.

The arrangement of the rest of the course should be devoted to a systematic method of making the more prominent chemicals, as also analytical work to determine the presence of substances in mixtures furnished the student, so that the general course of metals, acids, inorganic and organic bodies, that belong to pharmaceutical chemistry, can be covered. The reactions of chemicals in galenical preparations as are frequently prescribed should be prominently dwelt upon during the latter part of the course. Volumetric and urine analysis will be a fitting conclusion to such a course of instruction. Such a course should cover about twenty-five lessons as a minimum.

When it is not possible to introduce such a course of practical demonstrations and work as is outlined above, then from ten to fifteen hours should be given during each session, and one hour lectures with practical illustrations. This might include weights, measures, specific gravity, subdivision of drugs, division and dispensing of powders, the preparation of pills, and the galenical preparations in briefer scope than in the former outline; demonstrations showing the in-

compatibilities of chemicals with each other and with galenical preparations; and special attention to such prescription work as will best accord with the teachings of the professor of materia medica and therapeutics attached to the same institution.

THE DRAINAGE OF CHICAGO.

Read at the Seventeenth Annual Meeting of the Mississippi Valley Medical Association, held at St. Louis, Mo., Oct. 14-16, 1891.

BY JOHN B. HAMILTON, M.D., LL.D.,

SURGEON, AND FORMERLY SUPERVISING SURGEON-GENERAL MARINE-HOSPITAL SERVICE OF THE UNITED STATES; PROF. OF PRINCIPLES OF SURGERY AND CLINICAL SURGERY, RUSH MEDICAL COLLEGE; PROF. OF SURGERY, CHICAGO POLICLINIC; HONORARY MEMBER SOCIÉTÉ FRANÇAISE D'HYGIÈNE, PARIS, FRANCE, ETC.

The distinguished chairman of the committee of arrangements informed me that a short address of some kind would be required of me at this meeting, and that as the audience would not be confined to members of the Mississippi Valley Medical Association, some topic connected with public hygiene should be selected.

Being sincerely desirous to please my amiable friend, Dr. Love, I thought it might not be inappropriate to briefly consider a topic of interest to all the members of the Association, namely, the Drainage of Chicago.

There are some side questions connected with this subject that are of very great interest, and I shall refer to them, but the limitation of time will only afford opportunity for a statement of the sanitary problem, and of the manner in which those in authority propose to solve it.

TOPOGRAPHY AND CLIMATOLOGY.

Let us glance at the topography of Chicago as it was before artificially changed.

The oldest map of this region¹ is said to be still in existence in Quebec, and bears date of 1688.

Lake Michigan is correctly outlined, and the Chicago river properly placed and the French "Fort Chicago" located at its mouth. This map gives the formation of the Illinois river from the Desplaines and Kankakee. From the report of Surgeon-General Lawson,² in 1840, I quote the following:

"Fort Dearborn, lat. 41° 51' N., long. 87° 15' W. This post, now abandoned,³ is situated on the southwest shore of Lake Michigan, in the State of Illinois, twelve miles from the Wisconsin line. It is distant from the lake 250 yards, and is elevated fourteen feet above its surface. The river Chicago, which runs on the three sides of the fort, divides half a mile above it into two branches, the one north and the other south, in directions

¹ Davidson and Stuvé's History of Illinois.

² Statistical Report on the Sickness and Mortality in the Army of the United States, from January, 1810, to January, 1839. Washington, 1840.

³ Fort Dearborn was established in 1804. J. B. H.

nearly parallel with the lake shore. As the bank of the lake is several feet higher than the ground in the rear, the latter is sometimes covered with water. Indeed, the whole country is so low that in its early settlement boats frequently passed, during the spring floods, over the prairies from Chicago to the Illinois river. At this post the prairie opens upon the lake four miles wide, extending west beyond the reach of the eye. Above and below this point, the shore of the lake is densely covered with large forest trees, such as the different varieties of oak, ash and hickory. The soil is generally a rich loam; in some places clay, in others sand, predominating. Limestone is found in large quantities. . . . This position is one of our most salubrious military stations."

Dr. Drake⁴ in 1848, in his classical work, wrote: "Chicago, the commercial metropolis of Lake Michigan, stands on a low sand plain, on the western side of the lake. The breadth of this flat along the lake is about four miles, whence it runs back ten or twelve miles to the river Desplaines, an elementary branch of the Illinois. When the lake stood at a level only twenty feet higher than at present, its waters overspread this bed of alluvion, and a portion of them flowed down the Illinois. At this time it is a savanna, abounding in marshes and low sand ridges, traversed by the river just mentioned on the west and on the east by the north and south forks of the Chicago river, or creek; which, flowing nearly parallel with the lake shore, unite within it and form a short common trunk, which meanders through its centre to the lake. The water in this natural channel is twenty feet in depth, and rises and falls from the force of the winds upon the lakes about two feet; a fluctuation which tends to carry away the filth which would otherwise accumulate on its margins, from the houses on each side, and from the vessels which seek it, as the only harbor of Chicago. From the mouth of this river there is a gradual rise of the plain to the height of twenty feet; which may be attained by ascending the south fork of the river to a spot whence streams sometimes flow to the east and west on which canoes have passed from the lake into the Illinois river. The canal from Chicago to Peru now passes over that summit level which is the lowest between the Gulf of St. Lawrence and the Gulf of Mexico, being in round numbers only six hundred feet. Near the lake shore the winds are constantly blowing a fine dark colored sand on the margin of the plain, which south of town is raised into low ridgy dunes. The town-plat, from the destruction of the coarse aquatic vegetation, and the tramping of men and animals, is constantly becoming dryer and firmer. Beyond these influences much of

it inclines to marshiness; but as it is not subject to inundation and is high enough above the Chicago and Desplaines rivers to be drained by a judicious system of ditching, it will no doubt, as population increases, be entirely reclaimed. . . . In the year 1831 the town itself was commenced, and at this time, 1848, its population is near twenty thousand. The city is supplied with water from the lake, through a hydrant system; a growth so rapid indicates its prospective importance and entitles it to the regard of the Medical Topographer. . . . The statements of Doctors Boon, Davidson and Brinkerhoff fully sustained the impression made by the others (Brainard and Kimberly) and convinced me that the town of Chicago has been more infested with autumnal fever than Fort Dearborn had been; which goes to strengthen the prevalent opinion that the first exposure of the new soil to the sun, rain and air is insalubrious. A part of this upturning was by the plow, another by the spade in the excavation of the canal. This operation deserves some notice. The canal stretches southwesterly from the town completely across the plain. One of the contractors told me that in 1838 he had excavated a mile. The average digging was to the depth of four feet through a soft black mould, abounding in organic matter. The distance to which this silt was spread out on each side was such as to cover a parallelogram of the average width of two hundred and eighty feet exposed to the sun and rain. Nearly all who resided along the line of excavation sickened with autumnal fever; and almost all the laborers (Irish immigrants) suffered in the same way. Several died with malignant or congestive symptoms."

Such were the natural conditions, forty years ago, and now there has been placed upon the naturally unpromising site, more than a million of people, and it is estimated that since the census was taken there has been nearly two hundred thousand souls added to the population.

DRAINAGE.

Within ten years after the period mentioned by Dr. Drake, the river had become so contaminated as to cause uneasiness, and in 1855 the Illinois legislature passed an act creating the Board of Sewerage Commissioners, and in 1856 the systematic construction of sewers was commenced, and soon the Chicago river became what it now is, little else than an open navigable sewer. It soon became evident that some system of cleaning the river must be adopted, and in 1860 the sewerage commission recommended the widening and deepening of the canal. Not only to provide a sewer outlet, but to accommodate the increasing needs of commerce with the interior. This idea soon expanded into the project of a ship canal, which now seems near realization. The legislature,

⁴ On the Principal Diseases of the Interior Valley of North America. Cincinnati, 1850.

in 1889, passed "An Act to create Sanitary Districts and to remove obstructions in the Desplaines and Illinois rivers." This act created a Board of Trustees and gave them the necessary powers.

The Board have now completed the survey of the proposed canal route and are engaged in condemnation of the real property through which the canal must pass.

This conclusion was reached by the legislature only after exhaustive inquiry into the various plans proposed and the existing conditions, by the State Board of Health. That body reported, through its secretary, Dr. Jno. H. Rauch, who had for many years given the subject his careful attention, that the water supply of the city was endangered by the river emptying into the lake; and that the pumping works were inadequate to continuously change the current of the river; that sewage can not be profitably utilized as a manure, and taking out the solids by chemical treatment does not render it safe for domestic purposes; that seventy per cent. of the Chicago sewage passed down the Desplaines and into the Illinois river; and that the proposed canal would cost less than any other mode of the disposal of so large a body of sewage. The board further demonstrated in answer to the fear of those in the Illinois valley, that the river was already greatly polluted by the sewage of the several towns and cities in the Illinois basin, and that in the near future it would be necessary to flush the Illinois from Lake Michigan even if the Chicago sewage were otherwise disposed of.

The soundness of these arguments prevailed, and it is now proposed to construct a canal that will give a dilution to the sewage of 60,000 cubic feet per minute for each 100,000 of population, and not less than 24,000 cubic feet per minute when the population shall have reached 2,500,000.

The following tables were extracted for Mr. Artginstall from the report of the State Board of Health:

ANALYSIS OF WATER OF THE ILLINOIS AND MICHIGAN CANAL AND ILLINOIS RIVER.—("A.")

Parts per 1,000,000. Summer 1888. (Table from State Board of Health Reports.)

The Citizens' Association of Chicago, established in 1874, composed of most influential citizens, also warmly favored the Desplaines outlet system, and by many cogent arguments favored it. The only objection worthy of consideration that has been urged against this plan is the allegation that the danger to the people drawing their water supply from the Illinois river will be materially increased. This objection cannot be set aside by a general denial. They assert that pathogenic germs in sewage are not destroyed by dilution and that the solid matters are simply deposited with silt on bars and shoals. This view has lately been strongly supported by Frankland at the Congress of Hygiene and Demography, held in London, Aug., 1891. Frankland asserts that chemical evidence of the self purification of the waters is insufficient, that there must be a bacteriological examination as well. He admits, however, that sedimentation, (or the subsidence of solid particles) carries with it a very large number of microbes, and the fact remains that dilution, oxidation and sedimentation are so far the only known means of comparative purification of running streams.

Of these the current belief is that dilution is most efficient factor, and its effects on sewage is the same as is observed in the dilution of gas from chimneys. No one claims the destruction of noxious gases, but when poured into the open air they become so diluted as to be practically harmless.

At the same time it cannot be too strongly urged upon municipal authorities, that contaminating substances be kept out of running streams as much as practicable. Garbage can always be burnt, and other substances can be disinfected before being turned into the sewer.

But notwithstanding these precautions, and notwithstanding the great dilution proposed, in my judgment, intercepting sewers, to be constructed on each side of the river, and the lake front as well, will inevitably become necessary with the growth of the city.

THE WATERWAY SIDE OF THE QUESTION.

I have thus far only reviewed the case from

the standpoint of the sanitarian. There is another view almost as broad, and that is from the standpoint of the publicist. This involves the question of the physical effects of creating a new river 200 feet wide and 18 feet deep, the probable lowering of the lake level; the economic results of the vast waterway thus created, by providing means for increase of traffic, and additions to the trade of the valley, and the political effects of the closer commercial relations between the people on the borders of the lake, river and gulf, but as my time has already expired, I will refer you to the excellent paper of Mr. McMath, C. E., of St. Louis, and the elaborate one of Mr. Cooley.

DEFORESTATION.

I cannot close without reference to a topic of the utmost demographic importance to this entire valley, and that is, the subject of deforestation.

The National Conference of the State Boards of Health which met in Nashville, May, 1890, adopted the following resolution:

Resolved, That recognizing the well-known evils resulting to the whole nation from the disastrous floods which within recent years have taken place along the valleys of our great rivers; and from the destructive cyclones which from time to time occur, both of which evils have been pointed out to be due mainly to the cutting down of the forests on the mountains and along the hillsides where our great rivers take their origin, and to the violence which the wind storms obtain blowing over great tracts of practically treeless prairie, this National Conference of Health Officers desires most earnestly to bring these evils to the attention of our Federal government, our State and provincial legislatures, and other scientific and commercial bodies, urging them to take such comprehensive action as will (1) cause a survey to be made of the gathering grounds of our great rivers. (2) Preserve, and replant when necessary, these areas, with protective forest trees. (3) Establish schools whereby the principles and practice of forestry will be taught, and protect by the most stringent legislation the results of the above mentioned work. (4) Make recommendations to our towns and cities to form park associations for the planting of trees and obtaining possession of waste lands to be gradually reforested.

Last year at about this season, I made a journey through Italy and saw the Appenines extending from the north to the south of Italy, as an almost treeless, rocky ridge. The soil had long ago washed down the sides, and the almost everlasting rocks stand out as monuments of the ignorance and wastefulness of man.

We, in this yet new world, should realize that deforestation means general devastation, and that unless checked, our country may also become a desert. We may see in the orient, what may be the result of the fatalistic doctrine of "letting posterity take care of itself," and we may see in the example of Germany a nation strong and vigorous, that guards its forest trees as the "apple of its eye."

We have the power to stay the floods, to regulate the seasons, to preserve the natural water courses, and prevent much disease by increasing

the tree bearing area, and surely our countrymen have wisdom enough, and patriotism enough to lend their influence toward reforesting of all waste lands, and the establishment of parks in every village.

CAMPOR-MENTHOL IN CATARRHAL DISEASES.

Read at the Seventeenth Annual Meeting of the Mississippi Valley Medical Association, held at St. Louis, Mo., Oct. 14-16, 1891.

BY SETH S. BISHOP, M.D.,

OF CHICAGO.

SURGEON TO THE ILLINOIS CHARITABLE EYE AND EAR INFIRMARY, ETC.

While engaged in experimenting on an improved inhaler for catarrhal patients I observed that menthol crystals and camphor gum formed a clear, oleaginous liquid on coming into contact with each other. It occurred to me that such a combination ought to have a beneficial action in catarrhal affections of the nose and throat.

I mixed equal parts by weight of camphor and menthol, and combined 20 per cent. of the resulting fluid with 80 per cent. of lavoline.

¹ Discussion on the Levels of the Lakes as affected by the proposed Lakes and Gulf Waterway by Messrs. Wisner, Cooley, Haupt, Herschel.

The first case in which I tried its effects was one from which I had removed hypertrophied tissues from the right nasal cavity and used the cautery in order to open the passage way, not only for breathing purposes, but in order to facilitate the introduction of the Eustachian catheter.

Before operating in the opposite nostril I had fallen upon this mixture and used it with such results as to render an operation on the left side unnecessary. After making one thorough application with the De Vilbiss atomizer, I found the mucous membrane blanched, the turbinate bodies shrunken, the canal considerably increased in size and the discharge diminished. The patient experienced decided relief from the stenosis.

At another treatment, on introducing the Eustachian catheter through the nostril I had cauterized, its presence provoked a violent and protracted paroxysm of sneezing. This persisted so long that it was impracticable to insert the inflator into the catheter. I managed to throw a spray of the camphor-menthol into the nostril containing the catheter. At once the sneezing stopped and did not return, so that there was no further difficulty in injecting remedies into the middle ear.

That experience led me to try it in nervous catarrh. I had just received a letter from a hay fever sufferer in Tewksbury, describing his satisfactory experience with menthol and albolene inhalations which I had recommended last year.

The relief obtained by him, Professor Lockwood and others, by the use of menthol, and the fact that the presence of camphor appeared to intensify the effects of menthol, made it reasonable to suppose that this combination would afford relief in hay fever.

The first case of hay fever in which I used it was one of the early form. A spray stronger than 10 per cent. of the mixture with 90 per cent. of lavoline, produced sneezing and temporary stenosis of the nostrils, followed the next day by increased freedom of respiration and a sense of nasal comfort. A 5 per cent. solution produced no sneezing or stenosis, but, on the contrary, left the nasal passages patulous for several days.

Another patient, living in a suburban town, began using camphor-menthol combined with lavoline just before the usual time for her attacks to begin, and enjoyed immunity from the suffering by inhaling it two or three times a day. She is unfortunately located, being surrounded with the luxuriant vegetation of the country, and it speaks well for the remedy that it was able to keep the disease at bay. The last time she came for treatment, she had been able to prevent the development of the paroxysms, although she had noticed occasionally some premonitory symptoms. She brought me some specimens of the ragweed in full blossom, and notwithstanding that she at-

tributes her suffering every year to the pollen of this plant, she was free from its effects then.

One of my assistants, Dr. Hall, did not receive so much benefit from these inhalations. While they gave him temporary relief from sneezing and stenosis, the symptoms would return again in a short time. In this instance the remedy was less effective than in any other in which I have employed it, but he used a 24 per cent. solution in lavoline, which is too strong for sensitive noses.

However, it is not to be expected that any single inhalant will prove equally successful in all cases. And the pathology of the disease leads me to believe that no local medication alone will ever prove completely remedial in hay fever.

Within the past few days, ex-President Lockwood, of the United States Hay Fever Association, has written me as follows:

"You can safely say some very good things for the camphor-menthol spray and inhaler. For twelve years I have been driven to the White Mountains every summer on account of hay fever, and I am used to expect a serious relapse on my return home. Last year this relapse was very serious, and accompanied with severe asthma. This year I prepared the camphor and menthol, and I had no more than started from the Jefferson station when sneezing began, but I checked it at once with the inhaler. It was simply an ounce bottle, with wide neck and glass stopper. My use of it, and the comfort following, was noticed by some of my fellow sufferers, who understood well what it meant. A number of them used it freely, with pleasant results, and that little bottle was the good genius of the journey.

"The heat and dust made our return to the city the most uncomfortable in twelve years' experience, and yet, to the surprise of myself and friends with me, this was the first time of my getting through a return trip with no hay fever or asthma, and it was due to the camphor-menthol inhaling. In mild forms, or at an early stage of this malady, both spray and inhaler are very effective. Since my return home, the heat, humidity and dust-laden air have brought the malady on again in great force, but the camphor-menthol greatly ameliorates my suffering. During this incessant day and night asthma, the spray keeps the nasal passages open, and so far its help is grateful to the asthma."

I take this occasion to pay a tribute to Professor Lockwood's microscopical researches, and to his unceasing endeavors during the years of his presidency of the United States Hay Fever Association to direct its work along the lines of scientific investigations concerning the cause and cure of hay fever.

Dr. B., of Kansas, came to have me operate for opening up the nostril, and for ear treatment. It was impossible for him to breathe through the nostril, so greatly hypertrophied were the turbi-

nates. To pass the smallest Eustachian catheter was out of the question. I succeeded in getting the effect of a 25 per cent. solution in the anterior and posterior nares, with the result of opening the canal in one treatment sufficiently to afford nasal respiration and sufficient space for catheterization. Another treatment increased the freedom of respiration, and subsequent treatments maintained the patulous condition of the nostrils, thus obviating the necessity of any operation with the knife, saw or cautery.

While writing these observations, an old college classmate, Mr. H., of Hutchinson, entered my office, suffering from an attack of acute laryngitis. He was unable to speak aloud. I gave him two inhalations during the forenoon, first with a 5 per cent. solution, and later with the 10 per cent. The following morning his voice had returned with nearly the customary strength and smoothness. After one inhalation more, his voice became normal, and all symptoms of laryngitis vanished.

One of my assistants, Dr. Collins, restored his voice from an enforced whisper to a good speaking condition in twenty-four hours by treating an attack of laryngitis with the inhalations, varying in strength from 10 to 20 per cent.

In hypertrophic nasal catarrh, with excessive discharge, a 25 per cent. solution, *i. e.*, 12½ per cent. each of the camphor and menthol, and 75 per cent. of lavoline, has checked the discharge, given it a healthy character, and restored nasal respiration.

I have had four assistants conducting experiments parallel with mine. The experiences of two have been briefly referred to. One of the others, Dr. Davey, reports having obtained results corresponding to mine, and the fourth, Dr. Campbell, compares the action of camphor-menthol with that of cocaine, excepting the powerful anæsthetic effect of the latter.

The important point to be emphasized in the use of this, as well as other potent remedies, is the choice of the proper strength in adapting it to each individual case in order to secure the best results. In chronic hypertrophic rhinitis in a person of dull sensibilities, a 25 per cent. solution may be used with excellent effect; whereas, in the opposite extreme of temperament, in which the Schneiderian membrane is exquisitely hypersensitive, a first inhalation stronger than the 3, or 5, per cent. solution, may appear to act as an irritant.

I have injected a 10 per cent. preparation in lavoline into the Eustachian tube, which was closed so firmly that it was impossible to inflate the middle ear by the Valsalva or Politzer method, with the result of opening the tube so well that on the following day there was no difficulty in injecting remedies through it into the tympanic cavity. This has occurred repeatedly.

No ill results have followed the injection of 5 and 10 per cent. solutions into the middle ear, but in several cases of catarrhal affections of that cavity the hearing was improved and the head has felt clearer after the injections.

I have applied the full strength camphor-menthol to eczematous eruptions and found that it relieved the pruritus and reduced the swelling and redness. It had a similar effect in herpetic eruptions.

Finally, camphor-menthol contracts the capillary blood-vessels of the mucous membrane, reduces swelling, relieves pain and fullness of the head, or stenosis, arrests sneezing, checks excessive discharges and corrects perverted secretions.

70 State street, Chicago.

SHOULD PHYSICAL RESTRAINT BE USED IN THE TREATMENT OF THE INSANE.

BY ARTHUR LOEWY, M.D.,

ASSISTANT PHYSICIAN COOK COUNTY HOSPITAL FOR THE INSANE.

A question important both to the physicians in charge of the insane, and to the general public, is, "Shall physical restraint be used in the treatment of the insane?" This question has agitated the minds of officials in whose charge the insane have been placed, and has been for them a difficult problem to solve. I think that I may justly claim that those who have been intimately connected with this work will say that physical restraint, when properly and judiciously used, is a very important factor in the intelligent care and treatment of the insane. Physical restraint may be used for the following objects: First. To prevent the patient from injuring himself or herself. Second. To prevent the patient from injuring others. Third. When, for some bodily injury or ailment, it becomes necessary to apply restraint to secure proper action of some therapeutic reagent. Fourth. When patients remove their clothing. In those cases of insanity where there is a disposition on the part of the patient to injure him or herself, by thrusting the hand through window panes, by attempts of self-injury by throwing himself or herself on the floor, or by striking the head against the wall, or if the patient be suicidal, and make the most desperate attempts at self-destruction, the question arises, How shall we restrain this patient so that he may not injure himself, nor succeed in accomplishing that which is so dreaded in all hospitals for the insane, namely: suicide? The general public, as a rule, holds up its hands in horror when some sensational report is circulated by the press, that patients in a given asylum have been seen who had their hands in restraint, some strapped to the bench—or even greater,

when it is said that a patient has been seen in a strait jacket. In all such cases as I have cited above, our first object must be to restrain the patient by carefully watching his every move, and prevent the carrying out of those designs of self-injury or self-destruction. But in doing this we must have a requisite number of attendants, so that no bodily injury be done in caring for him. In most of our public institutions we find so

that patient's mental condition. It is simply a means of protection to those patients who are in the same ward, and to those in whose charge this particular patient may be. In the treatment of any number of the insane, the care of each case has a bearing on every case in the same ward. Hence, to prevent injury to other patients, and oftentimes even to preserve their lives, restraint must be applied. For either of these conditions, namely: a patient attempting self-injury or injury

Truax, Greene & Co.

Truax, Greene & Co.

many patients of the class I have just depicted, that it is an utter impossibility to assign to this special duty a sufficient corps of attendants. It is under these circumstances that physical restraint is justifiable. If a patient attack other patients in the ward, he must be so restrained that he can do no injury to others; at the same time it must be taken into consideration that restraint in this case cannot be called beneficial to

to those about him, the following means of restraint suggest themselves: First. The patient is seated on a bench, a strap is fastened around the patient's waist and through the arm of the bench. Second. The wristlets. Third. Mittens and muff. Fourth. Strait jacket. Should a patient in a paroxysm of furor attack those about him, and other means having failed, physical restraint becomes necessary, I would give preference to the

first means. I have repeatedly seen, in my association in the care of the insane, patients rapidly become quiet and composed when fastened to the bench. Should, however, this fail to accomplish the end desired, namely: to prevent the patient from injuring him or herself or other patients, some other means must be employed. In such an event I should prefer wristlets, and following this the muff and mittens. For female patients, should the first means fail, the strait jacket, properly applied, is much more to be preferred. I have already stated that the care of one case has a bearing on all other cases in the same ward, and should we fail to use restraint when a patient attacks those about him, we may by this neglect cause direful results. A blow administered by one patient to another is as quickly returned, and the excitement of such an encounter will only add fuel to the fire, and patients heretofore quiet become maniacal and pugilistic. In all such cases, restraint must be used before injury, be it great or small, can be done. Seclusion of patients is to be deprecated; no patient, because he becomes maniacal, should be forced into a room and locked there until the furor has passed away. It is here that the acuteness of the insane may be manifested, and self-destruction be accomplished in a very short time.

The next condition in which physical restraint must be employed, is for the intelligent treatment of the insane when suffering from some bodily injury or ailment. A patient who has injured the upper extremities by thrusting them through window panes, or who has sustained an injury, as dislocation or fracture; or when local applications must be made, the patient resisting all attempts to properly care for him, restraint must then be applied. The question which then presents itself is, "What kind of restraint shall we use under these conditions?" If splints have been applied to the arm, wristlets, mittens or the muff are useless, because in their application there would be great danger of shutting off the blood supply. Again, if the injury were one of the hand, it would be impracticable. Again, the old strait jacket is impracticable, because we could not watch the circulation, and if frequent changes of dressing were necessary, it would be a hindrance to proper treatment. To replace all modes of restraint in this class of patients, I have made improvements and additions to the old strait jacket, a cut of which is herewith shown.

The Benson Strait Jacket, as this is known, consists in having an opening in the front corresponding to the one in the back, and further, an opening in the sleeve from the neck to the tips of the fingers. By means of this jacket, a patient being confined to bed with some ailment requiring constant use of poultices, the poultices can be changed without raising the patient to the sitting posture, as must be done when the old

jacket is used, thereby avoiding the dangers of death from heart failure. The opening in the sleeve permits the physician to have knowledge at all times as to the condition of the injured member, and should swelling ensue after the application of a splint or cast, immediate knowledge can be had of the fact. An attachment is placed at the elbow, which is brought around the back and fastened to the cord at the tip of the fingers, thereby permitting each arm to be put in restraint separately. Thus we may place less tension on the injured arm than we would on the uninjured one. In the old jacket, each arm when in restraint has equal tension on it. I desire here to call attention to the fact that, when the jacket must be used as under the first and second conditions cited, it will be found that if the arms are tightly drawn, they are thus placed in an unnatural position, and pain is the result. If, though, this attachment placed at the elbow be brought around and tied to the cord at the tips of the fingers, the arms will be placed in a natural and comfortable position, as may be seen in the figure before alluded to. The fourth condition where physical restraint is justifiable, is where the patient removes his clothing. For the prevention of this object, we may use all the restraint I have already cited, the kind of restraint being wholly governed by the mental and physical condition of the patient.

For the maniacal we must use the jacket, the muff, mittens or wristlets. For cases, though, of melancholia or dementia, where the patient attempts the removal of clothing, I have devised a canvas wristlet, made thus: A piece of canvas is taken, somewhat larger than the size of the wrist. Parallel with the longest side of the cloth, two oblong openings are made. The loops are then cut in this same piece to fit in the openings made before, and through these loops a belt is drawn, and fastened in the back. The advantages of this canvas wristlet are these: First. There is less idea of restraint in their use, and they cannot injure the patient. Second. They can readily and easily be made. Third. Cheapness in construction.

I have thus laid down the four conditions under which I hold physical restraint to be justifiable. Never, I hold, should restraint be used as a punishment for misconduct. Never after a patient has done what he should not, but to prevent him from doing that which tends to his own disadvantage, and which prevents or postpones the recovery of his mental health, or for the safety of others, should restraint be applied.

PROF. JOHN J. REESE has resigned the chair he has so long filled in the University of Pennsylvania. His successor has not yet been appointed.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE \$5.00

SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,

No. 68 WABASH AVE.,

CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, OCTOBER 24, 1891.

SYPHILITIC SPONDYLITIS IN CHILDREN.

At the recent meeting of the American Orthopedic Association, DR. JOHN RIDLON, of New York, read a paper with the above title.¹ He says "syphilitic spondylitis differs in no way from syphilitic joint disease located elsewhere, except as it is modified by its peculiar surroundings. In the superficial joints, where the infiltration of the soft parts and bone can be readily seen and felt, the onset of the disease is very slow, and months may pass before pain is complained of or disability become serious; but in the spine, where the lesion is located in and about the anterior surface of the vertebral bodies, far beyond sight and touch, the slow advance of the early symptoms escapes recognition and the onset usually appears to be comparatively rapid. On any motion the distant pain is complained of, and sometimes within a few days the patient is unable to stand without support. If located in the dorsal region, the kyphosis soon appears with a sharp angle, formed of but one or two spinous processes, and with a long sweeping curve above and below. In the lumbar region, the kyphosis is slow to appear, often not appearing until marked psoas-contraction can be made out, and perhaps not until an abscess has formed; but lordosis is an early and well-marked symptom."

The description certainly affords no clue to the differentiation of this supposed syphilitic disease and the common tubercular joint, and the author admits that his earlier efforts to establish this disease met with so much resistance at the hands of his colleagues that he did not even publish his original paper, written some five years ago. Moreover, his cases, when examined, were pronounced by others to be tubercular. Nevertheless, he still feels convinced that syphilitic disease of joints, closely resembling the tubercular disease, does exist. He claims that the syphilitic disease shows a tendency, like syphilis elsewhere, to hyperplasia rather than to molecular disintegration.

The diagnosis is made chiefly upon the detection of syphilis in the parents or grandparents, and upon the presence of other syphilitic lesions in the child. RIDLON calls particular attention to the age of the child, and expresses himself as believing that in children under three years of age spondylitis, associated with chronic disease of some other joint, or in another portion of the spine separated by a healthy area, is more frequently syphilitic than tuberculous.

In this connection it is interesting to recall the observations of FOURNIER on late manifestations of hereditary syphilis, particularly the bony lesions. FOURNIER describes these lesions under three forms,—osteo-periostitis, gummy osteo-periostitis, and gummy osteo-myelitis. The first of these is probably closely connected with the conditions described by DR. RIDLON. Syphilis certainly by preference attacks the epiphyses of the bones. In the case of the lower end of the femur this may certainly very closely resemble disease of the joint. However, according to FOURNIER, the tibia is the bone most frequently attacked in late syphilis, and following this the radius and humerus.

By way of treatment RIDLON makes use of both mechanical and medicinal means. He finds rest in bed preferable to braces as a rule. Internally he uses mercury and iodine in large doses. If the stomach will tolerate it, one-thirtieth to one-twenty-fourth of a grain of the bichloride or biniodide, is given with five to forty grains of potassium iodide three times a day.

Whether DR. RIDLON be correct or not, he certainly has obtained some good results in treatment, and it is always wise in medicine to ques-

¹Med News, Vol. LIX, p. 453.

tion a single cause which is credited with being always responsible for a certain morphological lesion.

WAVES OF ZYMOTIC INFLUENCE.

At irregular periods we are called upon to chronicle the passage over our country of a contaminating, epidemic influence that manifests itself at various points with more or less virulence. In some localities the wave seems to be but a gentle breeze, as shown in an outbreak of scarlet fever attacking very many children, but easy of management, and followed by few, if any, deaths. Another locality develops a focus of diphtheria that has in it all the characteristics of a veritable cyclone. Those who are stricken with the disease, are so overwhelmed with the poison as to be at once clasped in the arms of the grim monster, and in spite of all known remedial measures the victims quickly succumb to his fatal embrace.

The present season will be remembered as one of extended epidemic influence, in which every considerable centre of population has suffered to some extent from the blow; and while the Nation rejoices in the season's most bountiful yield of the earth's fatness, very many communities are stricken and in mourning because of the zymotic wave that is passing over the land.

A mournful thought in this connection is in reference to the fact that in nearly every instance the effects of this pervading influence might have been ameliorated, by a recognition and enforcement of known sanitary laws.

Small-pox has been literally driven from our country's bounds. Absolute isolation of first cases will stop threatened epidemics of scarlet fever and measles. Typhoid, whether produced by a microbe or a ptomaine, is preventable by a removal of the cause of the infectious poison. This poison is known to be most frequently taken into the system through the drinking of polluted water or contaminated milk.

As the country and cities become more and more densely populated the danger from these sources increases, thus making a continuous demand upon physicians and health authorities for a never ceasing vigilance.

A most important duty is the education of the people, and particularly the youth who are in school, in regard to the causes of infectious diseases and their prevention.

Diphtheria is very prevalent in a neighboring city (South Bend, Ind.). This disease is known to be propagated not only by direct contagion, but indirectly through the inhalation of a poisoned or contaminated atmosphere. The unsanitary conditions of the city referred to are such as to continue the influences of the infectious disease that is carrying many of its children to an untimely grave.

At considerable expense the streets have been sewerred, but singular as it may appear, the council persistently neglect or refuse to compel householders to make proper connections therewith.

In the city of Chicago there were more than 200 deaths last month from typhoid fever, which would indicate not less than 2,000 cases in the city at that time, nearly every one of which was produced either by drinking the lake water without sterilizing by boiling, or by the use of milk in a similar manner.

The health authorities of every city should exercise the greatest care in seeing that dairy cows are provided with a sufficient supply of pure water. Two hundred deaths a year is quite a severe penalty for any city to pay for neglect in obtaining a potable water supply, but when the tax runs up two hundred deaths per month, such a wail should go up to the powers that be, as to permit neither sleep nor rest from superhuman efforts to right the wrong that exists. The question is not so much one of financial cost as one of life and health.

We are glad to know that the physicians of the city are fully alive to the importance of this momentous subject. Concerted action on the part of the medical profession would have a wonderful influence in forwarding the work of the Water Works Board and Drainage Commission.

TYPHOID FEVER.

The subject of typhoid fever was considered at the Chicago Medical Society, on the evening of the 21st inst. Four papers were presented, and the three hours session proved to be of great interest. The opening paper by DR. N. S. DAVIS, Jr., on the "Etiology of Typhoid Fever," was confined to the discussion of the subject as developed during the last eighteen months. He paid full and careful attention both to those who ad-

vocated the causative agency of the KOCH-EBERTH bacillus, and those who doubted it. Leaning, himself, to the view that the weight of the argument is in favor of the KOCH-EBERTH bacillus, he gave very full expression to the views of VAUGHAN that typhoid fever is not a specific disease, but a group of diseases caused by a variety of poisons. VAUGHAN considers that it is essentially a filth disease, arising under conditions resembling in general those concerned in the production of cholera infantum. In the discussion VAUGHAN'S work in the production of pseudo-typhoid bacilli was brought out. By subjecting certain microorganisms found in drinking water, to continuous high temperature, resembling that met with in typhoid fever, VAUGHAN has found that they lose their original properties and acquire the peculiarities heretofore supposed to be distinctive of the KOCH-EBERTH bacillus, viz., a resistance to stains, and the formation of an invisible growth on potato. RODET and ROUX by similarly treating the *bacterium coli commune*, find that it likewise acquires these same properties. On these grounds it is urged that the means of recognizing the KOCH-EBERTH bacillus being uncertain, the views which have already been expressed regarding it, based on this mode of recognition, must be held in abeyance. Quite recently this matter was reviewed somewhat fully in these columns.

The "Complications of Typhoid Fever" were discussed by DR. JOHN H. CHEW, and the "Treatment of Typhoid Fever" was the subject of DR. WILLIAM E. QUINE'S paper. DR. QUINE paid particular attention to the subject of the temperature, and made a strong plea for the temperature as the leading symptom in typhoid, and as the principal index for treatment. The excellent effects of the systematic use of the cold bath were strongly presented, and the reason of their effects laid to the door of temperature reduction. He does not advocate, however, the indiscriminate use of the baths in all cases, as is urged by their extreme advocates in Germany, and admitted that they favored the occurrence of relapse. He also urged a discriminating use of the modern antipyretics, but discouraged their prolonged employment.

The concluding paper of the evening was by DR. WELLER VAN HOOK, on "Laparotomy in Perforation in Typhoid Fever, and Report of a

Successful Case." In DR. VAN HOOK'S case the perforation occurred during the second week of the disease, and the operation was made about four hours after the accident. He made a small incision in the median line, and found the perforation quite readily. Discarding trimming the edges of the wound as unnecessary and as consuming valuable time, he closed the opening by three rows of LEMBERT sutures. Regarding the perforation as probably the only one, no further examination of the bowel was made, but the wound immediately closed after a proper *toilette* of the peritoneum. The fever continued its usual course for two weeks longer, and the patient made a complete recovery.

This is Dr. VAN HOOK'S third laparotomy for perforation in typhoid, and his first successful case. In reviewing the literature of the subject, Dr. VAN HOOK found that altogether there have been nineteen laparotomies performed for this condition with four recoveries. In some of these cases, however, the diagnosis is doubtful, typhoid not being positively distinguished from appendicitis. Rejecting the doubtful cases, the statistics show twelve laparotomies with one recovery.

To Dr. VAN HOOK, then, belongs the honor of the first undoubted successful operation for typhoid perforation.

ETHYLENE BROMIDE IN EPILEPSY.

DONATH has given in the *Therapeutische Monatshefte*, some considerations favorable to the adoption of the above named drug as a substitute for potassium bromide, in those cases where the latter cannot be continuously used without occasioning disagreeable symptoms, which troubles are for the most part chargeable to the potassium in DONATH'S opinion. He therefore sought for a bromine preparation in which the action of the latter would be highly accentuated and at the same time more pleasant than in the combinations that have hitherto been chiefly employed. Accordingly he has tried ethylene bromide in ten cases for several months, and is enabled to report that in all these cases, he regards the action of his new remedy as more happy than the potassium salt. The greater number of these cases had been of long standing and some of them had for years been under the influence of potassium bromide. Under the ethylene

these cases have shown an improved condition for the present; the convulsions have been diminished in force and reduced in frequency. In some, the convulsions are brought to a point where it is proper to describe them as mere muscular contractions with the customary loss of consciousness. Fifteen other cases have been under treatment a shorter period of time, too short, in fact, to warrant any declarations as to their improvement. DONATH recommends the following prescription: R. Ethylene bromide, spirits of wine, āā 32 minims, oil of peppermint, 2 minims. Dose: Five to fifteen drops three times daily. This dose may be raised to seventy drops, two or three times daily, for adults; or as high as twenty drops for children. It should be borne in mind that one minim of the ethylene is equal to two drops. The taste of the drug is sweetish at first, but afterwards leaves a burning impression. Its odor reminds one of chloroform. It is soluble in water and milk, and miscible with alcohol or oil. Its administration may also be effected by capsules containing three or four drops of the drug mixed with six drops of the oil of bitter almonds. This drug should not be confused with bromide of ethyl, which has been used to some extent during the past year as an anæsthetic.

EDITORIAL NOTES.

MR. J. HARRISON WHITE, the former business manager of this JOURNAL, is in no way connected with its management, and has no authority to make any statements in regard to its present conduct or affairs.

DR. THOMAS F. WOOD.—Dr. Wood, of Wilmington, N. C., has been chosen to succeed himself, in the Board of Health of his State, as Secretary and Treasurer for a term of six years. He is one of the representatives of the State Medical Society, duly elected by ballot at the last joint session of State Society and State Health Board.

LARYNGEAL TASTE.—Michelson has made, under Langendorff's direction, some careful experiments as to the distribution of the nerves of taste to the under or inner side of the epiglottis, and the results have been published in Virchow's

Archiv. The presence of the end organs, the taste bulbs, have been frequently noted, but the demonstration of a recognition of sapid substances has first been clearly made by Michelson. His tests were conclusive, with control experiments by electrical contact, the "electrical taste," so that it may be accepted as proved that the nerves of taste have in part a laryngeal distribution.

MEDICAL POPULATION OF CANADA.—The *Montreal Medical Journal*, quotes the following as a correct estimate of the number of practitioners in the Dominion, arranged by provinces:

Ontario	2,300
Quebec	1,100
New Brunswick	170
Nova Scotia	300
Prince Edward Island	60
Manitoba	140
Northwest Territory	50
British Columbia	60
Total	4,180

AN INCOMPATIBLE OF SODIUM BROMIDE.—According to the *Medical Press*, the following incompatibility has been pointed out: When solution of sodium bromide and cocaine hydrochlorate are mixed the alkaloid is precipitated. The writer adds: "It will be well to bear this in mind, for with the cocaine merely suspended a serious, and, in an infant, even a fatal accident might easily result."

SOCIETY PROCEEDINGS.

American Dermatological Association.

The Fifteenth Annual Meeting was held at Washington, September 22 to 25, 1891, in conjunction with the Congress of American Physicians and Surgeons.

The meeting was called to order by Dr. F. B. Greenough, of Boston, who made the opening address.

The Report of the Committee on Nomenclature was made and after discussion was accepted.

The first paper read was by Dr. H. G. Klotz, of New York, entitled "Dermatitis Hæmostatica." It was discussed by Drs. Piffard and Bronson.

Dr. L. A. Duhring, of Philadelphia, followed with a paper, "Report of a Case of Universal Erythema Multiforme." It was accompanied by a colored portrait of the case and specimens of large plates of exfoliated epidermis shed by the patient during the latter part of the course of the disease. It was discussed by Drs. Hyde, Duh-

ring, Sherwell, Shepherd, Fox, Allen and Bronson. Dr. Shepherd asked if any drug had been administered for the rheumatism that was a marked feature in the case, to which Dr. Duhring replied, "No! The treatment had been entirely negative." Dr. Fox had seen a case somewhat resembling that of Dr. Duhring in which there was a question if the eruption had been caused by some drug that had been taken for a coëxisting gonorrhœa. He thought that it was a purely accidental occurrence. We often see cases of dermatitis exfoliation following other diseases, such as psoriasis.

Dr. Shepherd, of Montreal, then read a paper upon "An Unusual Case of Sarcoma involving the Skin of the Arm, requiring Amputation."

This was followed by a paper by Dr. S. Sherwell, upon "Multiple Sarcomata. History of a Case Showing Modification and Amelioration of Symptoms with large Doses of Arsenic." In the discussion Dr. Zeisler mentioned brilliant results in a case of lupus sarcoma for the administration of arsenic. In a case of pigmentary sarcoma he had given the drug without effect. Dr. J. C. White, of Boston, had seen good effects from use of the drug in one case of sarcoma. Dr. Robinson, of New York, had not had much success with arsenic. He believed that many cases of multiple sarcoma were in reality microbean in origin and not true tumors.

The next paper read was by Dr. R. B. Morison, of Baltimore, on "The Hypodermic Use of Hydrargyrum Formamidatum in Syphilis," which he recommended as a treatment of great usefulness, especially as a means to fall back upon in some cases in which older forms of treatment did not succeed, or in which such a plan as that of inunction was not practicable. He always used Merck's preparation and found that it did not cause much pain nor prove objectionable. He had never used any of the insoluble salts. In the discussion Dr. Corlett said that he had found hypodermic injections of mercury of great use in some cases, such as in those cases in which the stomach has given out. Dr. Klotz had employed hypodermic injections in syphilis. While it was doubtless of value in some cases, for most cases older methods of treatment are quite as good. Dr. Greenough said that while greatly interested in the subject of hypodermic medication in syphilis, he had found it impossible to get his patients to submit to it. He thought it was useful only in exceptional cases in which other plans could not be used. Its ultimate result was no better than that of other plans.

Dr. J. Grindon, of St. Louis, read a paper upon "Lichen Scrofulosorum," which gave rise to a long discussion. Drs. Robinson, Piffard, Sherwell, Shepherd, Corlett, Bronson and Greenough all had seen cases of this rare disease.

Dr. Sherwell, of Brooklyn, read a paper on

MULTIPLE SARCOMATA OF SKIN.

History of a case showing modification and amelioration of symptoms with large doses of arsenic.

The author, after pointing out numerically several interesting points, chief among which were, largeness of therapeutic dosage, tolerance of them by patient, complete and rapid subsidence of tumors under such dosage, rapid recurrence under suspension of same, originality of treatment instituted, etc., goes on to give a history of the patient with sarcomata, supplemented with a further history by Dr. John B. Wheeler, of Burlington, Va.

Dr. Sherwell removed in all, from this patient, thirty growths, some of which were quite large, one $3\frac{1}{4}$ inches in diameter; Dr. Wheeler about a year later in a series of operations removed the immense number of one hundred and seventy (170) large and small. In the interval between his leaving Dr. Sherwell's care and coming under that of Dr. Wheeler, he had interrupted or almost suspended treatment spoken of above, which had at the time of his leaving Dr. Sherwell caused the complete or almost complete disappearance of all growth. They recurred too rapidly for Dr. Wheeler to operate, when Dr. Wheeler adopted same internal treatment as that which Dr. Sherwell had instituted with the most decided and gratifying results, namely, the same rapid disappearance of the growths. The case ended by his leaving Dr. Wheeler's care in good condition and doing exceedingly well, irregularity or total interruption of treatment, and as before recurrences of growths, followed in a few months by death.

SECOND DAY—THURSDAY, SEPT. 23.

The Committee on Statistics made its report through its Chairman, Dr. J. H. Hyde, of Chicago.

This was followed by a discussion on "Tuberculosis of the Skin," which was opened by Dr. J. C. White, of Boston, who presented "Its Clinical Aspects and Relations;" by Dr. J. T. Bowen, of Boston, who presented "Its Pathology;" and by Dr. G. H. Fox, of New York, who presented "Its Treatment." In the discussion Dr. H. G. Piffard drew attention to the fact that French and other competent observers had surmised the connection between what was then called pulmonary consumption and lupus and the so called scrofuladermata. He had done so in 1878. Recent invention of the Abbe condenser and Zeiss lenses had enabled us to discover the tubercle bacillus, and to establish the relationship on pathological grounds. He himself believes that lupus erythematosus is fully entitled to the name "lupus," as he thinks that it, too, is of bacillary origin. Nor is he alone in his opinion. Cold abscess of the skin is probably due to the same cause, as is

also rodent ulcer. He would agree with Dr. White in believing that we should have some collective term for all the various tubercular diseases. In treatment he would advocate cutting out the whole diseased patch, unless it was very extensive. Next to the knife he would place the actual cautery after removal as much as possible of the growth with the curette. Arsenic and chloride of zinc are also to be depended on.

Dr. C. W. Allen commended multiple scarification and combined pyrogallol and mercurial plasters; he thought that there might yet be a future for Koch's tuberculin.

Dr. J. Zeisler was in thorough accord with Dr. White. By his experience at the Hospital, St. Louis, he had become converted to the use of the galvano-cautery. He would also testify to the efficacy of the solid nitrate of silver stick which, bored into the skin, would act both as a knife and caustic. He was not enthusiastic as to tuberculin.

Dr. E. B. Bronson believed that it was best to retain for some time our present terminology for the different tubercular diseases. In regard to tuberculin, he had seen improvement in some cases treated with it, but on the whole his experience had made him regard the remedy unfavorably. He had had good success with the dental burr, as first advocated by Dr. G. H. Fox. The nitrate of silver stick was also good.

Dr. J. N. Hyde was glad that Dr. White had come to accept local contagion as the cause of lupus, a view that he himself was among the first to advocate. He thought that in this country there were but few cases of lupus with a history of pulmonary tuberculosis in the family, or with tubercular diseases elsewhere. He did not believe in the treatment by scarification. Both the curette and nitrate of silver were serviceable in proper cases. In regard to tuberculin, he thought it possible that in time we might find something of value in it, but it was not so now.

Dr. L. A. Duhring would retain the old names for some time to come. He had not found lupus associated with general tuberculosis in private practice. He would recommend pyrogallol most highly, using it in the form of a plaster, with resin and soap plaster, three of the resin plaster and one of the soap plaster. This is to be worn continuously. Local use of bichloride of mercury he had not found beneficial. Tuberculin he had found helpful, though he did not report any case of cure.

Dr. P. A. Morrow would agree with Dr. White that as lupus and some other diseases had a common etiological factor, we should place them together under a common heading. He advocated the use of multiple scarifications, followed by mercurial plaster. For destruction of the small lupus nodules he recommended punctate cauterization with a white hot instrument. Chloride

of zinc was superior to pyrogallol as a caustic. Excision will probably increase in favor as the means of treating lupus.

Dr. A. R. Robinson would not include lupus under a common heading with tuberculosis on account of its different clinical aspect.

Dr. H. G. Klotz was not yet satisfied with our present knowledge of the infection of the skin with the bacillus tuberculosis.

Dr. L. D. Bulkley was not satisfied with any of the plans for the external treatment of lupus. Internally he has great faith in phosphorus as a curative agent, the nodules softening up and disappearing under its continuous use. He would corroborate Dr. Fox's advocacy of fuchsin. As to pyrogallol, that, too, was admirable. He applies it in powder form, pure, after scraping. Salicylic acid, combined with pyrogallol, is also useful.

Dr. S. Sherwell was doubtful of the relationship of tuberculosis to lupus.

THIRD DAY, FRIDAY, SEPT. 24.

Dr. Duhring read a paper upon "Notes of a visit to the Leper Hospital of San Remo, Italy." In reply to a question by Dr. White, after the paper was read, he replied that no attempt at segregation was made in San Remo. There were but few cases in the hospital and they were in an ordinary ward of a general hospital. They were not permitted to leave the confines of the hospital.

Dr. P. A. Morrow, of New York, then followed with a paper on "Skin Grafting," and showed a case in which the operation had been done by the method described by him and with admirable results.

In the discussion of the case Dr. Duhring spoke in high praise of the operation of skin grafting as practiced by Dr. Jas. E. Garrettsen. Dr. Clarke asked if Dr. Morrow thought that the inclusion in the graft of the deeper structures of the skin, as recommended by him, would give any better results than more superficial ones. To this Dr. Morrow replied that he thought they would be more certain to take, and he had had not a single failure. He had made more than fifty grafts of hairy skin upon a cicatricially bald scalp, and all of them had taken, and from many of them the hair was growing nicely. Dr. Sherwell had had good results, also, by deep grafts.

Dr. P. A. Morrow, of New York, then read a paper on "The Treatment of Alopecia Areata," and was followed by Dr. L. D. Bulkley, of New York, with a paper on "A Therapeutic Note on Alopecia Areata." The two papers were discussed together. Dr. L. Zeisler believed alopecia areata was due to a parasite, though perhaps there were some cases due to a neurosis. The latter were the very obstinate ones. He was in favor of treating all cases by epilation about the

patches. With pilocarpine he had had no success. He regarded the use of a concentrated solution of common salt as a good remedy for stimulating hair growth.

Dr. W. T. Corlett spoke in favor of acetic acid as a remedy in alopecia areata. Cases, however, recovered spontaneously.

Dr. G. H. Fox was always pleased to hear any one speak with confidence of any treatment of alopecia areata, as Dr. Bulkley had done of carbolic acid. He was rather skeptical of any remedy. A strong solution of ammonia had proved as effective as any in his hands. He thought that general treatment of the patient was quite as important as any local application. Dr. J. E. Graham had never seen any cases that would lead him to believe that alopecia areata was contagious. He did not think that because antiparasitic remedies were useful, that this was a proof of the parasitic nature of the disease. Dr. P. A. Morrow thought that there had been a sufficient number of cases of contagion reported to satisfy any reasonable doubt of the contagiousness of the disease. He quoted Eichhoff's report, in which a number of cases were traced to one barber. He had had one case of probable contagion.

Dr. L. A. Duhning said that in spite of a great deal of study of alopecia areata he had never been able to find any parasite in the disease, nor to be convinced that the disease was contagious. He believed that there was a disease simulating alopecia areata, and often reported as such, that sometimes occurred epidemically, but was not alopecia areata. He regarded arsenic taken internally as very valuable in the treatment of the disease. He could see no reason for depilating the healthy hair about the patches.

Dr. J. C. White said that we were still wanting positive evidence of both the parasitic and the neurotic element in the etiology of the disease. Clinical evidence points both ways. He had seen cases of apparent contagion. He had seen 30 cases of a disease simulating alopecia areata, and that were not cases of ring worm, occurring in an asylum, which probably were instances of the so-called contagious alopecia areata. He did not think that they were true alopecia areata.

His favorite remedy was half a drachm of croton oil to eight ounces of turpentine used daily. Of course it failed in some cases, as do all remedies. If it failed he used many other remedies that had been commended, but they did not do any better. He did not believe there was any specific remedy.

Dr. H. W. Stelwagon had never been able to trace a case to a contagious origin. Local stimulation is more to be relied on in treatment. He was fond of equal parts of turpentine, cantharides and tincture of capsicum, with arsenic internally.

Dr. J. N. Hyde believed that the time would come when alopecia areata would be regarded as a symptom. Some cases were doubtless parasitic and some neuritic in origin. In bad cases he used creosote locally. After say the 45th to 48th year of life the chances of recovery were greatly decreased.

Dr. H. G. Klotz had had one case in which hereditary syphilis was probably the underlying cause, the boy getting better when under specific treatment.

Dr. C. W. Allen believed that the disease was parasitic and thought that he had in his own practice observed a case of contagion. He thought that internal treatment was valuable. Naphthol and pefrogallal had both proved useful in his hands.

Dr. S. Sherwell believed the disease to be of neuritic origin alone. Stimulation was most to be depended on.

Dr. J. Grindon had never met with a case that suggested either a parasitic or contagious origin of the disease.

Dr. F. B. Greenough used in practice a half drachm of carbolic acid in an ounce of water.

Dr. L. D. Bulkley in reply to a question of Dr. Morrow, said that he used the 95 per cent. solution of carbolic acid only to a small portion of the scalp at a time. It should be brushed over lightly at first so as to benumb sensibility and then rubbed in more thoroughly. He had not used it elsewhere than on the scalp. The skin is red for a few weeks; this disappears and the hair grows. He also administers strychnia and phosphoric acid, and keeps up the nutrition of the patient.

Dr. R. W. Taylor, of New York, read an account of a case of "Angioma Pigmentosum of Atrophicum," by Dr. A. W. Brayton of Indianapolis. It was accompanied by an excellent portrait.

Dr. J. C. White stated that his investigations showed that the disease was not limited to Russian Jews, but was met with also in persons of English and French descent.

Dr. Bronson then read his paper upon "The Etiology of Pruritus."

THIRD DAY, AFTERNOON SESSION.

It began with a short discussion of Dr. Bronson's paper on "Pruritus," in which Drs. Zeisler and Morrow took part, the discussion being closed by Dr. Brown Bronson. Dr. W. T. Corlett, of Cleveland, then read a paper upon "Diseases of the Skin, Associated with Derangement of the Nervous System." It was discussed by Drs. Bronson, White, Fox, Duhning, Zeisler, Allen and Sherwell, who took various views of the cases reported, all agreeing that it was very difficult to diagnose what the cases were without having seen them.

Dr. L. A. Duhring read his paper entitled "Experiences in the Treatment of Chronic Ringworm in an Institution for Boys." He recited the many remedies he had used. In the discussion Dr. G. H. Fox said that Dr. Duhring's experience was both interesting and valuable. He had had considerable experience in the New York Skin and Cancer Hospital. He had found chrysarobin useful, as had Dr. Duhring. He began the treatment by clipping the hair short, and shaving, either only over the patches or over the whole scalp and applying chrysarobin in traumatization. He was tired of greasy applications. Hydronaphthol plaster, as recommended by an European physician, had proved more satisfactory than chrysarobin. He advocated epilation where practicable.

Dr. J. Zeisler advocated pyrogallol as a parasiticide. Dr. Duhring, in reply to a question, said that some of the cases recovered in six weeks, and some not for a year. Dr. White thought that while chrysarobin was a good remedy, it was not a safe one to use outside of an asylum or hospital. He recommended a combination of sulphur, carbolic acid, and naphthol in ointment form. Dr. Stelwagon recommended an ointment composed of tar, sulphur, and citrine ointment. Dr. Sherwell advised keeping the scalp saturated with a mild oil and covered with a skull cap. Dr. E. Wigglesworth believed that it is necessary for us to have regard to the nutrition of our patients. Dr. C. W. Allen bore testimony to the value of chrysarobin. Dr. L. A. Duhring, in concluding, said that the cases were all well when he left off treatment, and that they remained well for at least one year. Epilation he found did not repay the vast amount of labor it cost. He regarded ointments as most useful remedies.

Dr. J. Zeisler, of Chicago, then read his paper on "Epilation; its Range of Usefulness as a Dermatotherapeutic Measure." In the discussion, Dr. G. H. Fox said that he was glad to hear any one advocate epilation in sycosis, as he had found it a most useful remedy. A sulphur paste after epilation is valuable. He had not found epilation so promptly curative as had Dr. Zeisler, while he laid more stress on diathetic management than did the latter. He was sure that epilation was useful in some cases of chronic ringworm of the scalp. Dr. H. G. Klotz spoke also in favor of epilation in sycosis, though he had cured many cases without it, notably with mild naphthol ointments. He thought epilation to be valuable in syphilitic lesions about the hairs, as well as in all the pustular affections implicating the hair. Dr. L. A. Duhring had not been able to practice epilation on his patients on account of the pain it caused, specially on the upper lip. He could not see much use in epilating in alopecia areata when the hairs were firm about the

patch. Dr. P. A. Morrow said that he did not think that it was necessary to pull out all the hairs about the bald patches, but it was a good thing to make traction on all of them and to remove all that were loose. Epilation was a requisite in all rebellious cases of trichophytoses. If the hair is removed by a quick sudden movement, the operation is nearly painless. Dr. H. W. Stelwagon believed that many cases of sycosis could be cured without epilation. He would speak in special praise of Fleming's solution in trichophytosis, diluting it at first one part to five or six of water, and gradually increasing the strength to just short of marked irritation. Dr. S. Sherwell spoke of the connection between catarrhal conditions of the nose and sycosis of the upper lip. Dr. J. N. Hyde said that the last time he was in London and Paris he had observed that epilation was quite generally practiced about the patches of alopecia areata. In closing Dr. Zeisler said that when epilation was properly performed it was almost painless. As he regards alopecia as a parasitic disease spreading at the periphery he epilated about the patches to prevent their spreading.

FOURTH DAY—MORNING SESSION.

The first paper was by Dr. J. E. Graham, upon "Molluscum Contagiosum." Dr. Bowen said that there was little question but that the disease was contagious. It is still unproven whether certain bodies found in molluscum are or are not coccidial. Dr. Allen had no doubt about the contagiousness of the disease, and related cases of the disease spreading in an asylum from one case. Excision is never necessary. They can readily be squeezed out, and then lightly touched with a caustic. He believed in their parasitic origin. Dr. E. Wigglesworth likewise cited a case of contagion. Dr. J. C. White, while believing that molluscum was contagious, was not prepared to accept the psorosperm as its cause. Dr. J. N. Hyde pointed out that in the statistics for the year just closed, seventeen cases of molluscum contagiosum were reported, viz.: nine from Boston, five from New York, two from Chicago, and one from St. Louis. Dr. F. B. Greenough believed them to be contagious. In treatment he simply bores them out with nitrate of silver stick. Dr. S. Sherwell concurred in the belief of their contagion. Dr. J. E. Graham thought, from evidence so far brought forward, that the so-called psorosperms were simply degenerated epithelial cells.

Dr. J. N. Hyde, of Chicago, then read his paper, "Note Relative to Pemphigus Vegetans." In the discussion, Dr. L. A. Duhring said that he had had the opportunity of seeing the case described, and would corroborate what Dr. Hyde had said of it. It certainly was more of the nature of pemphigus than anything else. Dr. Bowen

had seen a case of Neumann's in Vienna, and this one brought that one back very vividly to his mind. He regarded the term "pemphigus" as a most indefinite one, and thought that it gave very little idea of the pathology of the case under discussion. Dr. S. Sherwell had seen a case with analogous symptoms in a woman, which was cured by ovariectomy. Dr. J. E. Graham related the history of a similar case of his own. It became much better under arsenic, but suffered a relapse.

Dr. J. N. Hyde, in closing, said that in his case there was no disease of the ovaries. He regarded the prognosis in his case as not good.

Dr. H. W. Stelwagon then read his paper on "A Study of Mycosis Fungoides." It was discussed by Drs. Hyde, White, Hartzell, Bowen, Duhring and Fox. Dr. Hartzell emphasized the infectious nature of the tumors, and thought that we must look to inoculation experiments for its proof. Dr. Bowen spoke of the disagreement among pathologists as to the exact nature of the tumors. Dr. Duhring said that the disease was a general one of the skin, and did not seem to affect other organs to any extent. He believed it to be an infectious disease. It may be regarded as on the border line between an inflammatory new growth and a tumor. Dr. Fox related a case of apparent infection of the disease in the New York Skin and Cancer Hospital. He also spoke of the early diagnosis of the disease, and reported a case that at first looked like an eczema marginatum, but afterwards developed the characteristic tumors.

Dr. Stelwagon, in closing, said that he found, in looking up the literature of the disease, some fifty or a hundred reported cases. It was exceptional for the disease to begin as tumors.

Dr. M. B. Hartzell, of Philadelphia, then read his paper on "Lymphangioma Circumscriptum, with Report of a Peculiar Case." It was discussed by Drs. Stelwagon and Bowen.

Dr. H. G. Klotz, of New York, followed with a paper: "Remarks on Carbuncle, with Report of a Peculiar Case." It was discussed by Dr. Bowen, who spoke of the remarkable paper by Dr. Warren, of Boston, describing the pathological anatomy of the disease.

Dr. C. W. Allen then made some remarks on "Erythema of Nalvus Nuchæ." Dr. Zeisler thought it probable that erythema nuchæ was often due to pressure and rubbing. Drs. Fox, Duhring, Grindon and White also took part in the discussion.

Dr. J. Grindon read a paper on "A Case of Lichen Ruber." Dr. Zeisler would be inclined to view the case as one of lichen planus. In this disease plantar and palmar thickenings are apt to form. Arsenic often cures these patients. Dr. S. Sherwell agreed with Dr. Zeisler in his diagnosis, though the case presented many exceptional features; one especially being the involve-

ment of the nails. Dr. White believed the case to be one of lichen planus, and spoke of the uncertainty surrounding the whole question of the lichen group. Dr. Hyde said that he always found the polygonal outline of the papules to be well marked, something that does not seem to be familiar to the Germans and French. Dr. Duhring agreed with the previous speakers in this diagnosis. The polygonal shape and umbilication are often wanting.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

The health of the city continues to be in a very satisfactory condition. During the week ending September 12th 747 deaths were reported, representing an annual death rate of 23.05 per thousand inhabitants in a population of 1,690,076, against 822, the average number for the same week during the past five years, and the average rate 23.48. This is an increase of 11 on the mortality of the preceding week, and this slight increase was chiefly due to diseases of the respiratory organs. The deaths from this class of diseases were, bronchitis, 25, pneumonia, 51, and phthisis, 102. In contagious diseases there were 24 cases of measles, with one death, 80 cases of diphtheria, with 21 deaths, and 42 cases of typhoid fever, with 9 deaths. Diarrhoeal diseases, one fatal in 112 cases, and there were 341 deaths among children under 5 years of age. The births reported for the week exceeded the deaths by 258; which is unusual in this city; although it must be borne in mind that while the necessity of obtaining from the Health Department a burial permit in every instance secures the report of every death occurring in the city, the registry of births is by no means so complete.

It is generally conceded that an important factor in the preservation of public health in a great city is a cleanly condition of the streets, and the mayor of New York, in consequence of the representations of the Board of Health in regard to the unsatisfactory manner in which his duties have been performed, has very properly removed the Commissioner of Street Cleaning. In a communication addressed to the mayor on September 15th, President Wilson, of the Health Department, called his attention to reports of the regular monthly inspection of the streets for August, of a special inspection made on on the 14th, by sanitary officers of the Department, and of Dr. Morean Morris, Chief Inspector in charge of the Summer Corps of Physicians; after which he went on to say: "Cleanliness of the streets is regarded by this Department as most important to the public health, and it is apparent from the reports also referred to that their condition is far from satisfactory in this particular, and that this subject, for sanitary reasons, demands special attention."

It seems that some time ago the mayor asked the Board of Health to make a thorough inspection of the streets,

as regards their sanitary condition and the effect upon the public health; and it was upon the strength of the reports thus furnished him that he decided to take the step which he did. According to the city statutes now in force, the head of the Department of Street Cleaning is removable by the mayor, provided such removal meets with the approval of the Board of Health, whenever the mayor shall certify that to his judgment such removal is required in the public interest. It is needless to say that in the present instance when Mayor Grant had certified to this effect the Health Board promptly gave its approval of the removal of the Commissioner.

The new incumbent of the position, Mr. Thomas S. Brennan, who, it is believed, will conscientiously and thoroughly carry out the work he is paid to do, is a man with an exceptionally large experience in the administration of the charitable and criminal institutions of the city. Also, it may be stated, he has an exceptionally large acquaintance among the medical profession of New York, with many of the most prominent of whom he came in constant contact for a long period of years. This career in many respects is an interesting one. In 1859, at the early age of 16, he was appointed a night watchman at the Bellevue Hospital, and was soon promoted to the captain of the watch and night storekeeper. He was next transferred to Charity Hospital, on Blackwell's Island, where he became steward and deputy warden. In 1866 he was made warden of Bellevue Hospital, in which capacity he remained until 1875, when he was appointed one of the Commissioners of Charities and Correction; a position which he held continuously for fourteen years and eight months. These commissioners, it will be remembered, have charge of the affairs of all the hospitals, asylums, prisons, and other charitable and penal institutions belonging to the city.

Sanitary superintendent Wm. A. Ewing, who has just returned from abroad where he has been making a study of the sanitary methods in vogue in some of the principal cities, expresses the opinion that while the streets of New York are certainly kept as clean as those of most of the latter, so far as our sanitary regulations in general are concerned we are far in advance of any of the European cities he visited. The plumbing in the hotels and public buildings here, he says, is eminently superior to anything of the kind abroad, and our supervision and care of contagious diseases, he also states, are the very best that he has seen anywhere. While in London Dr. Ewing attended the International Congress of Hygiene and Demography, and he found that the exhibits sent by the New York Health Department were by far the largest and best there. He took with him to the Congress and placed on exhibition plans of the plumbing and drainage, and of the lighting and ventilation of some of the best tenement houses here, as well as the plans of older tenement houses which had been altered in order to improve their sanitary condition; and these plans excited so much interest among the sanitary engineers and architects present that at their request for more time to examine the exhibits he left them in London for a week after the close of the Congress.

There has lately been brought to this city a remarka-

ble case of parasitic growth, the subject of which, born in India, is known as the double bodied Hindoo boy. A number of physicians and others were invited to a private inspection of the lad at the Metropolitan Hotel, and Dr. George D. Bleything has made the following report concerning him: "I have examined the boy Laloo in the presence of Dr. W. G. Thompson, of the New York University Medical School, Dr. J. Blake White, of Charity Hospital, and a number of medical gentlemen and representatives of leading newspapers and medical periodicals, and find him to be a remarkable case of arrested development in foetal life. The boy himself is a fine, bright, well developed youth of eighteen years, and attached to the extremity of his sternum is the incomplete figure of a twin. The arms are given out, without scapulae, from the sternum of the young man. The trunk is short and incomplete, but it terminates in a pelvis with which the legs are connected. There would seem to be no separate heart in the parasite, and the pulse, both radical and axillary, is synchronous with that of the autosite. There is anchylosis of the joints in the undeveloped child. The young man is conscious of a sensation when this second body is roughly touched." It is said to be the opinion of competent surgeons who have examined the boy, that the parasitic growth could be removed without serious injury to him; but in that case his value as a museum "freak," which is now very great, would, of course, collapse. As it is, he does not appear to suffer much inconvenience from his unsightly incumbrance, and he is very agile in his movements.

P. B. P.

Illinois Army and Navy Medical Association.

Editor Journal of Am. Med. Assoc'n.—At the meeting of the Army and Navy Medical Association, held in Chicago, October 7th and 8th, the following resolution was offered and unanimously adopted, viz.:

WHEREAS, In view of our high esteem for Dr. John H. Rauch, as a medical officer of the United States Army during the war of the Rebellion, as a gentleman of worth and culture, and for his most efficient services as a member of the Illinois State Board of Health, whereby the sanitary conditions of the State and Nation have been greatly improved, the standard of medical education elevated, and the interests of profession and people most thoroughly guarded, therefore,

Resolved, That we hereby express our regret that so efficient a member of the Board of Health of the State of Illinois, should have retired from that body. No more active, efficient, earnest worker, can be found among the medical profession, to fill that important position, and we believe that the interests of the people as well as those of the medical profession, will be advanced by his recall to duty thereon.

Very respectfully,

EDWARD P. BARTLETT, Secretary.

Springfield, Ill., October 14th, 1891.

Lost Papers.

Editor A. M. A. Journal, 68 Wabash Ave., Chicago, Ill.

Dear Sir:—On yesterday the clerk of the Maxwell House here, handed me a package of papers, which proved to be the notes and original papers read in the Section of Practice of Medicine, at the meeting of the Association held at this place in May, 1890. They evi-

dently were lost, and only now have come to light. If you desire the package, I will forward it to you, as many of the essays bear the marks of careful preparation, and no doubt the authors would be glad to either get their copy again or have it published by you. Very truly yours.
J. D. PLUNKET, M.D.

Nashville, Tenn., October 17, 1891.

The misplacement and apparent loss of the papers of the Section on Medicine last year was a source of much trouble to the Editor of THE JOURNAL, and every possible means was used for their recovery. We are glad that even at this late date they are discovered, and suggest that the authors of those papers write to Dr. J. D. Plunket, of Nashville, enclosing stamps for their return.

BOOK REVIEWS.

MASSACHUSETTS STATE BOARD OF HEALTH REPORT FOR 1890. Boston: Wright & Potter Printing Company, State Printers.

The two volumes before us surpass in several points any previous publication by this State Board. Part I, containing 850 pages, is devoted to the examinations of water supplies and inland waters, made from 1887 to 1890, by engineers, chemists, biologists and health officials, under the supervision of Mr. Hiram F. Mills, engineer member of the Board, whose elaborate classifications and tabulations form the principal part of the first volume. Suitable maps, plates, photo-micrographs and charts abound in the two volumes. Part II, comprising 900 pages, describes the experimental investigation on the purification of sewage by filtration and by chemical precipitation, also on intermittent water filtration, and on the beginnings of bacteriological research, both as to water and sewage. This latter research is under the direction of Professor W. T. Sedgwick, State Biologist, and is the means of bringing to the front some original discoveries by Mr. E. O. Jordan, "in this new branch of sanitary science." The bacterial flora of the sewage examined at the Lawrence station was found to be large and various, some of which have not been hitherto described. The two species most frequently observed in the sewage of Lawrence were the *bacillus coli commune*, and a species isolated and named, for the first time, by Mr. Jordan, as the *bacillus cloacæ*. This report is ultra-technical in scope, it scarcely contains an allusion to typhoid fever, whereas in point of fact it is little else than an earnest and most laborious attempt to defend the State against the constantly advancing fever-foe.

ESSENTIALS OF ANATOMY AND MANUAL OF PRACTICAL DISSECTION, together with the Anatomy of the Viscera. Prepared especially for Students of Medicine, by CHARLES B. NANCREDÉ, M.D., Professor of Surgery and of Clinical Surgery in the University of Michigan. Fourth Edition, revised and enlarged by an appendix containing Hints on Dissection, by J. C. DA COSTA, M.D., based on the last edition of Gray's Anatomy. Thirty handsome full page Lithographic Plates, in Colors, and 188 fine Wood cuts. Philadelphia: W. B. Saunders. 1891.

The first edition of this work on the "Essentials of Anatomy" was issued in 1888, and it has proven to be

one of the most popular of "Saunders' Question Compend." That students of medicine, for whom it was especially prepared, have made a demand for it, is fairly indicated by the fact that this edition begins the fourteenth thousand placed on sale. It may, in many respects, be considered an epitome of Gray's popular work on general anatomy, at the same time having some distinguishing characteristics of its own to commend it. The plates are of more than ordinary excellence, and are of especial value to students in their work in the dissecting room. It can be recommended to them.

APPLETON'S SCHOOL PHYSICS embracing the results of the most recent researches in the several departments of Natural Philosophy. American Book Company, from the press of D. Appleton, & Co. 1891.

This first edition, prepared by J. D. Quackenbos of Columbia College, Alfred M. Mayer of Stephens Institute of Technology, Francis E. Nipher of Washington University, Silas W. Holman of Massachusetts Institute of Technology, and Francis B. Crocker of Columbia College, needs no further assurances than is given by their names and their official positions that the work is authoritative, and that it will be found to be useful.

Presenting, as it does, a view of Natural Philosophy, as interpreted and accepted with the light of modern science and investigation and thus brought fully abreast of the present day, it will be of especial service to students of medicine who have been denied the advantages of a collegiate training.

ATLAS OF CLINICAL MEDICINE, by BYROM BRAMWELL, M.D., etc. Assistant Physician to the Edinburgh Royal Infirmary, etc. Volume i, Part ii. Edinburgh: T. and A. Constable. The University Press. 1891.

Part second of this excellent work has just been issued and it is fully equal to the first part, recently issued.

This number treats of

First: Addison's Disease, clinical investigation of Addison's Disease. Two cases simulating Addison's Disease.

Second: Melanotic Sarcoma with Pigmentation of the Skin. Clinical investigation of cases of Melanotic Sarcoma.

Third: Hodgkin's Disease. Clinical investigation of cases of Hodgkin's Disease.

With it are superior illustrations of the text, and with additional plates showing Molluscum Fibrosum. Xeroderma. Pigmentosum. Mania.

Should the high standard which characterizes the two numbers of the work already issued, be maintained it will prove a valuable addition to clinical medicine that will be welcome and that should be so well supported by the profession as to encourage authors and publishers to issue more works of the kind.

ESSENTIALS OF PHYSIOLOGY. By HOBART A. HARE, M.D.

This is one of Saunder's exceedingly useful little compends, and is one of the best of question compends. The author has done his work thoroughly and well, and no one knows better how to present those points useful to the student than Dr. Hare. The plates of the cranial nerves from Arnold are superb.

MISCELLANY.

DR. THOS. F. RUMBOLD, of St. Louis, is now sojourning in California. Twenty-five years' exclusive office practice has undermined his health. He will remain there a year longer. His address is San Francisco, Hotel Pleasanton.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.—Preliminary programme of the session of the Southern Surgical and Gynecological Association to be held in Richmond, Va., November 10th, 11th, and 12th, 1891.

PAPERS TO BE READ.

The President's Annual Address, Louis S. McMurtry, M.D., St. Louis, Mo.

Remarks on Systemic Infection from Gonorrhœa, Illustrated by Cases, Bedford Brown, M.D., Alexandria, Va.

The Rational Treatment of Peritonitis Based upon the Consideration of the Pathological Conditions Present, W. D. Haggard, M.D., Nashville, Tenn.

A Medico-Legal Aspect to Pelvic Inflammation, W. W. Potter, M.D., Buffalo, N. Y.

Complications in Pelvic Surgery, and How to Deal with Them, Joseph Price, M.D., Philadelphia, Pa.

Cholecystotomy—Report of Case—52 Gallstones and 10 Ounces of Pus Removed—Success, W. B. Rodgers, M.D., Memphis, Tenn.

Some of the Complications of Psoas Abscess, J. McFaddin Gaston, M.D., Atlanta, Ga.

Laparotomies Performed in the Past Year, Thomas Opie, M.D., Baltimore, Md.

Imperforation of the Rectum, Geo. Ben. Johnston, M.D., Richmond, Va.

A Case of Induced Abortion for the Relief of the Nausea and Vomiting of Pregnancy, with Remarks, Christopher Tompkins, M.D., Richmond, Va.

The Principle of Drainage as Applied to Surgery of the Deep Urethra, F. W. McRae, M.D., Atlanta, Ga.

The Neuroses of the Genito-Urinary System in the Male, Frank Lydston, M.D., Chicago, Ill.

Nephrectomy, with Report of Cases, Edwin Ricketts, M.D., Cincinnati, O.

Venomous Serpents of the United States, and the Treatment of Wounds Inflicted by Them, Paul B. Barringer, M.D., University of Virginia.

A Report of Some Additional Cases of External Perineal Urethrotomy Without a Guide, J. Edwin Michael, M.D., Baltimore, Md.

Growth of Fibroid Tumors of the Uterus after the Menopause, Jos. Taher Johnson, M.D., Washington, D. C.

The Part the Shoulders Play in the Production of Laceration of the Perineum, with Suggestions for its Prevention, W. D. Haggard, M.D., Nashville, Tenn.

The Pedicle in Hysterectomy. How Formed; Its Subsequent Behavior; Its Final Condition, I. S. Stone, M.D., Washington, D. C.

A Case of Pelvic Abscess, John Brownrigg, M.D., Columbus, Miss.

A Case of Cyst of the Mesentery, with Remarks, J. A. Goggans, M.D., Alexander City, Ala.

The Female Urethra, K. P. Moore, M.D., Macon, Ga.

Medico-Legal Aspect of Intestinal Surgery, J. D. S. Davis, M.D., Birmingham, Ala.

Albuminuria; Its Relation to Surgical Operations, J. W. Long, M.D., Randleman, N. C.

Senile Gangrene, Frank Prince, M.D., Bessemer, Ala. Hemorrhage versus Shock, W. L. Robinson, M.D., Danville, Va.

Treatment of Gallstones, with Report of Cases, W. E. B. Davis, M.D., Birmingham, Ala.

(Title of paper not determined), Hunter McGuire, M. D., Richmond, Va.

(Title of paper not determined), Duncan Eve, M.D., Nashville, Tenn.

(Title of paper not determined), A. V. L. Brokaw, M. D., St. Louis, Mo.

(Title of paper not determined), Chas. A. L. Reed, M. D., Cincinnati, O.

(Title of paper not determined), W. F. Westmoreland, M.D., Atlanta, Ga.

LOUIS S. MCMURTRY, President.
W. E. B. DAVIS, M.D., Secretary.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from October 10, 1891, to October 17, 1891.

Capt. George T. Beall, Medical Storekeeper U. S. A., granted leave of absence for one month. During absence of Capt. Beall, Asst. Surgeon Chas. B. Ewing, U. S. A., attending surgeon, St. Louis, will take charge of the medical purveying depot in that city.

Captain Charles M. Gandy, Asst. Surgeon U. S. A., is relieved from duty with Army Medical Board, to take effect on its final adjournment, and ordered to Ft. Yellowstone, Wyo.

Capt. Robert B. Benham, Asst. Surgeon U. S. A., is relieved from duty at Ft. Hamilton, N. Y., and ordered to Mount Vernon Bks., Ala., for duty.

First Lieut. William N. Suter, Asst. Surgeon U. S. A., is relieved from duty at Ft. McKinney, Wyo., and ordered to Ft. Grant, Ariz., for duty.

First Lieut. Harlan E. McVay, Asst. Surgeon U. S. A., is relieved from duty at Ft. Mackinac, Mich., and ordered to Ft. Wingate, N. M.

First Lieut. James D. Glennau, Asst. Surgeon U. S. A., is relieved from duty at Ft. Riley, Kan., and ordered to Camp Oklahoma, Oklahoma Ter.

First Lieut. Merritt W. Ireland, Asst. Surgeon U. S. A., is relieved from duty at Jefferson Bks., and ordered to Ft. Riley, Kan.

Capt. John M. Banister, Asst. Surgeon U. S. A., granted leave of absence for four months.

First Lieut. William N. Suter, Asst. Surgeon U. S. A., granted leave of absence for one month, to take effect on or about October 15, 1891.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending October 17, 1891.

Surgeon A. F. Magruder, ordered to the "Boston."

Surgeon W. S. Dixon, detached from the "Boston," and granted leave for two months.

P. A. Surgeon E. H. Marsteller, ordered to special duty at Baltimore, Md.

P. A. Surgeon N. H. Drake, detached from the "Albatross," and granted leave for two months.

P. A. Surgeon F. W. F. Wieber, detached from the "Pensacola," and ordered to the "Albatross."

Surgeon George P. Bradley, detached from Naval Hospital, Chelsea, Mass., and ordered to the receiving ship "Wabash."

Asst. Surgeon F. G. Braithwait, detached from the "Wabash," and ordered to Naval Hospital, Chelsea, Mass.

P. A. Surgeon H. G. Beyer, ordered to Naval Academy, Annapolis, Md.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Three Weeks Ending October 10, 1891.

Surgeon John Vasant, granted leave of absence for twenty-three days. October 8, 1891.

Surgeon W. H. Long, granted leave of absence for thirty days. October 1, 1891.

Surgeon J. B. Hamilton, to represent the Service at the meeting of the Mississippi Valley Medical Association. October 2, 1891.

Surgeon J. H. Gassaway, leave of absence extended five days. September 28, 1891.

P. A. Surgeon W. A. Wheeler, granted leave of absence for thirty days. October 7, 1891.

P. A. Surgeon C. T. Peckham, to represent the Service at the meeting of the Mississippi Valley Medical Association. October 2, 1891.

P. A. Surgeon W. D. Bratton, granted leave of absence for thirty days. October 7, 1891.

P. A. Surgeon W. J. Pettus, to proceed to Norfolk, Va., for temporary duty. October 2, 1891.

P. A. Surgeon G. M. Magruder, granted leave of absence for twenty days. October 7, 1891.

P. A. Surgeon R. M. Woodward, granted leave of absence for thirty days. October 6, 1891.

Asst. Surgeon G. T. Vaughan, granted leave of absence for thirty days. October 6, 1891.

Asst. Surgeon J. O. Cobb, to proceed to Buffalo, N. Y., for temporary duty. October 7, 1891.

Asst. Surgeon G. M. Guiteras, to proceed to Mobile, Ala., Pensacola and Mullet Key, Fla., on special duty. October 10, 1891.

Asst. Surgeon B. W. Brown, to report to the medical officer in command, San Francisco, Cal., for duty. October 3, 1891.

ADDRESSES.

THE WORK OF MEDICINE FOR THE WEAL OF THE WORLD.

BY H. C. HUGHES, M.D.,
OF ST. LOUIS, MO.

*President's Address before the Seventeenth Annual Session of the
Mississippi Valley Medical Association.*

MEDICAL PROGRESS.

It is gratifying to the humanitarian student of scientific medicine to note the amazing progress lately made in knowledge of the human organism and in resources for its regulated control in health and disease.

Since Democritus, in that classical garden at Abdera, made one of the earliest dissections, to learn thereby, if possible, the morbid nature of melancholia, such strides toward a knowledge of the nervous system and its diseases and their treatment have been made as would have impressed the physicians of antiquity with the belief that their modern brethren were sorcerers and charmed men bearing charmed lives. Much of this has taken place within the past three decades, for when I entered the profession but little compared to now was known of the wonderful mechanism and normal function of the nervous system and its not less astonishing morbid manifestations, as we study and treat them today. True, the astonishing anatomical discoveries of Sir Charles Bell and of Claude Bernard into the intricate function of the nervous system, which with the amplifications of Solly, Abercrombie and other anatomists of the brain and spinal cord, and the contributions of our own Brown-Séquard, then an American and the pioneer neurologist of our country and foremost in the world, had already attracted the attention of neurological *savants*; but not an American or European school had then a chair of Neurology or Psychiatry, though Rush had, nearly half a century before, clinically described some mental diseases in the Pennsylvania hospital in advance of all the world across the sea; and his descriptions have been lately verified, approved and re-affirmed at home and abroad as evidence of our present advance in Neurology.

Notwithstanding the great discovery of Sir Charles Bell respecting the spinal nerves had long before been announced to the world, the diseases of the sympathetic nervous system were then scarcely known, and are only now beginning to be generally recognized and studied. True, the great works of Rokitanski, and Kolliker, and Trousseau, were before the world, the great, the venerable Virchow was fast winning converts to his cellular pathology, the fame of Charcot as a great clinician was rapidly spreading, and Romberg had written a work on nervous diseases destined to endure; but neurology, as a special department of medical study, was not then much considered by the profession at large, though Charcot and his European *confrères* had begun to bring it into the special prominence it has since acquired. Graves and Marshall Hall, Solly and Abercrombie, Stokes and Skoda, had made their everlasting impress on the profession. The treatment of fevers had been placed on a rational basis, and the science of physical thoracic exploration and descriptive anatomy were almost as perfect then as they are now.

Velpeau, Civiale, La Rue and Nélaton, Mott, Mussey, Mütter, Stone, McDowell and Pope, with the rising Brainard of Chicago, and the surgeons of Great Britain and Germany, had made, or were making, the surgery of the middle third of the nineteenth century lustrous and renowned: The work of Corvisart had become common property; the cell doctrine was being taught; ether and chloroform were in use; and Bastian and his colleagues were vigorously and with plausibility contending for spontaneous generation against the old, but now re-affirmed and firmly established maxim: "*Omni vivum ex ovo*."

The classical and revolutionary psychiatry and psycho physiology of Maudsly, the psychology of Herbert Spencer, and the discoveries of Ferrier, had been only dimly foreshadowed in the theoretical misconceptions of Gall and Spurzheim, and in the discovery of Broca's speech center in the third left frontal convolution of the cerebrum. Aphasia was then only known as the alalia of Lordat—an indifferent condition of the brain affecting speech without involving the intellect, and the great contest between Broca and Aubertin

before the Anthropological Society of Paris, that determined the beginning of cerebral localization as a fact of physiological science, had ended in Broca's surrender and later triumph. It is true that Pinel had already broken the shackles of the fettered lunatics of Bicetre, while Chiarugi had done the same for the chain-bound and imprisoned insane of Italy. The elder and younger Tuke, of England, were practicing and proclaiming humanity to these unfortunates in the pioneer land of the Magna Charta and habeas corpus; and Combe had said and proved that insanity was a disease and not a satanic possession, nor a proof of the anger of the gods; yet, in the profession at large, comparatively little was understood of insanity, or nervous diseases in particular. At that time, to be afflicted with many now well-known diseases of the nervous system, was to be dismissed by the physician, without attempt at treatment, as only nervous; and the unfortunate subject of hysteria, often regarded as a she-devil, who might do better if she would, because a dash of cold water in the face or down the spine brought back to its unfortunate victim the latent, abdicated, or dormant, volitional control of the higher over the lower rebellious and riotous nerve centers, got but little sympathy. Epilepsia, too, was still in the minds of some physicians, and more laymen, the *Morbus Sacer* which no mortal could control; while chorea still retained the name of the patron Saint Vitus, who was supposed to have had the power to stop the grimaces and jerky movements and sometimes diabolical dance, of this psycho-motor and motor center disturbance.

Brown-Séquard, and that Manchester physician, whose name I cannot now recall, who preceded him in the use of the bromides, have helped us to dispel many a theological delusion through therapeutic resources.

How unfortunate that the profession had not possessed them and the knowledge we have of their therapeutic power in the time of Cotton Mather, and of the convulsionaries of the middle ages.

It was before our day that Bayle and Calmiel described the general paralysis of the insane, and Prichard that of moral insanity; but only in your day and mine that they have come to be recognized as distinct morbid conditions of mind, though now often differently designated as paresis, parietic dementia, dementia paralytica, affective insanity, paranoia, etc.

In our day, imperative conception, morbid impulses, the *folie de toucher*, and the *folie du doute*, of the French, or the mysophobia of Hammond, and the numerous pathophobias of Beard, are studied as conditions requiring medical aid; and insomnia, as the symptomatic portentous expression of a functional or grave cerebral disease, and constipation in certain persistent forms, as a

nervous disease, are just now being studied and treated in a more judicious manner than even ten years ago. The judicious physician no longer contents himself, or satisfies his patient, with only a hypnotic in the one instant, or a cathartic to empty the sewer which soon fills again, in the other. These are but temporary expedients. Any druggist, especially if he be rash enough (and many of them have no lack of that therapeutic confidence which is always present where knowledge is least) can do this.

These patients require, in addition to temporary relief, rested and restored brains, and a reinvigorated sympathetic nervous system, especially in that of one or other of their great splanchnic cavities.

Neurasthenia, or, as I have called it, general functional neurastrophia, has come to light in my time. Doctor Van Dusen, of Kalamazoo, Michigan, and Beard, of New York, who were the first of all modern observers to describe it, were personally known to me, the latter at the time his first paper was published on the subject, and oh! what a world of woe has been saved to man and woman by the discovery—especially to woman! To be weak, exhausted, and unstable in one's nervous system is to be miserable; but to be thus miserable and unappreciated by both layman and physician, as these persons were before it was known that people might be exhausted in their nervous systems without an appreciable local disease, was pitiable in the extreme.

The doctor, searching for a *locus morbi*, and finding none in the heart or lungs, liver or other of the viscera, and none in the brain or cord, or at least nothing deemed adequate to the general nervous weakness, and, perchance, finding in poor woman some slight local displacement or catarrh, or, perhaps, even an ulceration, or some ovarian tenderness, a part of the general hyperæsthesia, or an ovarian congestion that was but part of the lowered vasomotor tone which allowed of arteriole failure of control and vascular fullness there, as elsewhere, in the organism, too often too hastily saddled all the blame on the disordered but unoffending organ, "more sinned against than sinning;" and attacked with knife, cautery, or mechanical scaffoldings, the local part for the physiological fault of the whole. The violence done to confiding woman in the name of surgical therapy, the needless mutilation of her special anatomy in the name of surgical gynecology, are not yet fully appreciated; but, thanks to the spreading light of neurological truth, the clitoridectomies of the past, the oöphorectomies and hysterectomies of the present, except chiefly for real local surgical cause, are likely soon to be relegated to the surgery of the more barbaric past; and normal ovariectomy for distant neuropathic perversion will no longer be a recognized surgical procedure. Enlightened gynecology, en-

lightened surgery and neurology are now agreed to this.

Knowledge broadens with enlarging surgical skill. To be only a good cutter is not now regarded as necessarily the best of surgical counsellors, and in the practice of surgery caution and conservatism have come to be regarded in the profession as the proper accompaniments of boldness and skill with the knife. Surgery learns caution and conservatism from widened experience, just as therapeutics has learned that the hypodermic syringe is a dangerous implement when unwisely handled, or just as obstetrics has learned that the forceps may be too handy and applied too often. On the latter subject the *Centralblatt für Nervenheilk* reports the investigations of Winkler and Wallen to the end that the forceps in delivery was a more frequent cause of idiocy than was commonly supposed. In a *post mortem* examination of an idiot sixty years of age, who had been delivered with forceps, a depression of both parietal bones, corresponding to cerebral lesions, was found. Out of ten subsequent autopsies of idiots one similar condition was found to exist, and out of twenty-five living idiots six were found to have depression of the skull.

Medical progress within the last few years has been especially gratifying, aside from having exceeded that of many years before in the many therapeutic discoveries already mentioned, most of which have been made within the past five or six years, such as the coal tar analgesias, hypnotics and Liebreich's cantharadinate of potash.

We have the discovery of Morvan's disease within the past eight years, the elucidation of syringomyelia and recently the approximative identification of the two as probably Morvan's and Maries' varieties of the same disease, the discovery and differentiation of neuritides from the ataxias and clearer descriptions of paranoia. The first account of that singular trophoneurosis of the bony system, acromegalia, discovered by Marie, was made in 1866, and Salemi Pace has cleared up the subject of astasia and abasia, under the title of "Partial Spinal Amnesia," so late as 1888.

But it would weary you to give a full detail of progress, even in the department of neurological medicine, made within the past year.

Let me just epitomize a little further some of the remaining most important advances, only to index them in your minds. To the reflexes have been added the virile, or bulbo-cavernous, the anal and oral, for diagnostic purposes.

To Bright's disease insanity has been added as a symptom, though this was known before. The psycho-pathology of the genic sense, and its aberrations, has been especially elucidated since the name of "Jack the Ripper," of Whitechapel notoriety, came before the public. The opium

psychosis, likewise alcoholism and dipsomania, have been much elucidated the past year. Additional cases of that curious phenomenon, *Seelindolndheit*, or soul blindness, have been recorded, and Monk has extended the visual area of the cerebral cortex. The relation of the blood to insanity has been more satisfactorily studied, and a marked deficiency in hæmoglobin has been found among the insane. This recalls the once despised assertion of Rush, that insanity is a disease of the blood-vessels.

Buckhard has attempted the treatment of hallucinations by cutting into the ideogenic area of the brain, and in one case claims to have actually succeeded, but he will probably find few followers. Luys has elucidated the subject of chronic hallucinations, finding coarse morphological change in the paracentral lobule perceptible to the naked eye. Alcoholic neuritis, as well as other forms of polyneuritis already alluded to, has been markedly cleared up during the past year. The microbe of tetanus has been confirmed, and Ferrier's cerebral localization, in the main, still stands the test of critical, clinical and pathological experience.

In psychotherapy, the tranquilizing power of galvanic cephalic electrization, as a promoter of sleep, has been confirmed and admitted. Codia in the opium habit, and as a substitute for opium in the management of the hyperæsthetic neuropathies, sulphonal, amylene-hydrate, chloralamide, hypnol, hyoscine, phenacetine, exalgine, antipyrin, and a long list of new hypnotics, have come into practical use, while chemical synthesis signalizes one of the greatest triumphs in its history in the production of an artificial quinine, absolutely identical with the product of the cinchona tree, from a Brazilian shrub (*remijia pedunculata*), treated with iodine and chloride of methyl (thanks to MM. Grimand and Armand), while experimental physiology has proven that tolerance of and resistance to the zymotic diseases, and marked immunity from them in many instances, may be secured by protective inoculations, out of which, also, have grown Listerism and the safe, grand and painless surgery of our day—a surgery of half a century's growth, to which all the surgery of all the past in the world's history does not compare.

Congenital myotonia, as a disease of muscle, due to a persistence of or reversion to the embryonic type of muscular tissue, has been proven this year by Deliege. The pathology of athetosis has been shown by the younger Hammond, and Hachin demonstrates anew the neurotic theory of cholera. New proofs of the influence of the nervous system upon abnormal pigmentation are being constantly brought forward, and dermatology is paying large tribute to dermo-neurology in other directions, notably the eczemas.

These notes of progress show that medicine is

not standing still, but keeping up with the procession, and what is being done in my special department, is going on all along the line. What an inspiring record of discovery have we now, and what a prophecy for the future! If it be the proudest possible boast of a man to-day to be a physician abreast of the present advance in medicine, what may it be in the generation that shall come after us? What would Hippocrates think, could he now see what great results have flown from that early and faulty dissection of his friend Democritus, to which I have alluded? and what an amazing advance has been made since Vesalius, braving the superstition of his times, and even impending death for his temerity, dared to make the first human dissection. Though the atrabilis for which Democritus sought was but a myth of the imagination, from attempts like that of Democritus, grew Galen's proof that the arteries contained blood and not air, Harvey's and Jenner's great discoveries of the circulation and vaccinia and Claude Bernard's demonstrations of vaso-motor arteriole control, and Sir Charles Bell's discoveries in connection with the great sympathetic nerve.

The age that has so perfected the implements of war as to make peace profitable to all the world, that has given us the sewing machine, the telephone, the phonograph, the graphophone, the electric car for surface and aerial travel, sending man around the world in an incredibly short space of time, and sending audible messages with lightning speed of his journeyings back to his home, has given us resources in medicine and surgery equally astounding—discoveries and resources in biology, and in physiological and chemical therapy, so surprisingly grand and useful, that skepticism is silent, and criticism has become optimistic of nearly every professed novel resource of legitimate science. The favorable reception, for example, of Koch's recent incomplete discovery, is in marked contrast with the early rejection, by the profession, of the discovery of Jenner, for on the discoverer of vaccinia was bestowed, in the earlier days, aversion and contumely almost equal to the threatened anathemas of the Church upon the devoted head of Galileo.

Science is now having its innings. The patient labor of her two or three past decades is bearing fruit in medical channels for the welfare of mankind, far beyond the fondest hopes or the most exaggerated expectations of the past. The miracles of modern medicine are simply marvelous beyond all past conception of possibility. The wondrous, but unwise and unstable and morbid results of modern hypnotism, as commonly practiced, are not at all comparable to the real and permanent and safe results of modern scientific therapy—medical and surgical, and the latter are in marked contrast with the fatal mischief

of the modern mind-cure craze. Yet, in hypnotism and the faith-cures of the day, medical science discerns the influence of the psychical over the physical, and judiciously employs it. It understands and correctly interprets, though at variance with that of the ages that are gone, the significance of the royal or sacred touch—the miraculous power of priest, potentate or healing fountain. This interpretation is found in the demonstration of Salpêtrière, La Charité, and the modern miracles of Nancy. Bernheim, Charcot, Paul Richet, Luys and Braid, who preceded them, have given the explanation.

The marvelous results of modern psychotherapy scarcely exceed the effects which follow judiciously applied electrotherapy, to say nothing of anæsthesia, and the modern resources of the later *materia medica* proper, in systemic and local disease. The power to control symptoms fills the mind of the modern physician with amazement and his heart with thankfulness, as he compares it with the comparatively meagre resources of the past. Pain in disease is practically under his perfect control; insomnia, no matter how grave the morbid condition with which it may be allied, is no more, while the manifestations of febrile action may, whenever desired, be entirely subdued, the problem being only when to stop it. Modern therapy is to the modern physician, in regard to aberrant function, almost what the throttle valve is to the engineer of our day. Now pain and heat, sensibility, and the heart's and the mind's morbid impulses, are controlled and regulated at the will of the physician; the cerebral, gastric, intestinal, renal and hepatic functions obey him, if he be fully as skilled as he may be, with all the resources of his art at full command—not with unerring certainty as yet, but with a degree of promptness and accuracy never before attained by our science and art. Truly, we live in an era of wondrous and most gratifying resources in medicine, and the triumphs of the present and recent past give us buoyant hope of even greater victories over disease in the near future.

If I have appeared to dwell too much upon neurological progress it is partly due to the fact that advance has been especially great in this department of medical research, partly to the fact that being the first neurologist who has ever been elected to preside over this body, it is probably expected that I should discuss medical progress from my especial stand-point, but my chief reason for so doing is the great and greatly appreciated influence of the nervous system and neurotherapeutic agents in the causation, phenomena and treatment of disease, so great that neural pathology has now a place almost paramount in medical thought, so that the clear view of Cullen that all diseased manifestation is largely nervous, is being confirmed by discov-

eries of our day, and the advances of the century since the great nosologist wrote, tend to confirm his now famous dictum: "*Quantem ego video motus morborum fere omnes motibus in systemate nervorum ita pendent ut morbi fere omnes quodammodo Nervosi dici queant*," words I love to quote, though uttered over a century ago, because every year of medical observation since they were written has proved their truth. But in every department of medical investigations we are in the midst of wondrous scientific surprises. The orchitic fluid of the great French physiological *savant*; the remarkable inoculations of his colleague, Pasteur; the researches of the great Berlin bacteriologist, Koch, whatever we may think of his tuberculin, have only been transcended by the wondrous laparotomies of Lawson Tait, inaugurated by our own immortal Ephraim McDowell, the brilliant craniotomies of Victor Horsley, the abdominal sections of Nicholas Senn, the surgical antiseptic triumphs of Lister and their colleagues. The cranial topography mapped out by Ferrier and previously pointed to by Hitzig and Fritsch have opened up the old *terra incognita* of cerebral physiology and pathology to the advance of the neurotherapist and neurophysiologist, and we are infinitely blessed in the present age over our ancestors in the manifold resources of insight and of relief afforded by our art in desperate extremes of despairing suffering.

SPECIALISTS AND SPECIALISM.

The recognition of special work in the vast field of practical medical therapeutics has passed beyond the control of the old foggy element who delight in decrying specialism, and while there is great danger of specialism becoming "priggish" and hobbyish, this danger can be averted by cordial recognition and fraternal relation of specialism with general medicine. The true specialist should be largely a consultant to the general profession and mainly indebted to it for his practice.

Specialists need only become markedly distinct in the public eye through the profession at large neglecting to give timely and proper recognition and to amalgamate them with the mass in Medicine that makes up the grand salvation army of the race, physically and mentally speaking. We are approaching a day, too, when the territory of the specialist in Medicine will become common ground. The early coming auspicious day should be hailed by all true physicians. Specialism is simply the advance picket guard which explores the ground ahead and ascertains if it be proper ground for occupancy by the grand army of Medicine, and sooner or later, the whole will take up its line of march and go forward to possess it.

MORAL AND SOCIAL RELATIONS.

Physicians, as a class, are honest men. Pro-

fessional pride is founded largely in candid dealings with patients. The welfare of the patient is the first law with us, and no body of men has ever had so plain a moral plank in its platform of principles as ours. The precept of the golden rule has gleamed through the conduct of the profession in all ages. It was introduced practically in the Hippocratic oath and to-day no body of men stand before the world in a more disinterested or more honest light than does the medical profession. We hold the profoundest secrets of the family with the sanctity of the professional and few of us are ever charged with filching from our patients for considerations of benefit without reasonable hope of benefiting them.

We are often charged with incompetency, but seldom with dishonesty—never justly the latter, for medicine, whatever her faults of head, has none of heart towards mankind. She is the peer of all professions, the ministry of the Gospel of the immaculate Immanuel not excepted.

The incompetency of regular medicine is the incompetency of human imperfection only—the incompetency of the times in which we live, not the lack of endeavor. Notwithstanding we live in an age that has given us the electric light, we still see some things as through a glass darkly, but it is safe to say that our profession partakes as much of the general illumination of the present age as any other of the practical arts and sciences. We have utilized the electric light in exploring the obscurest recesses of the body and the lightning in treating its diseases. We are chasing the bacilli to their lairs and seeking to solve their pathological or physiological and hygienic significance.

HOW MEDICINE HAS HELPED MANKIND.

Medicine benefits mankind in a thousand ways not appreciated without the profession, even as "the light shineth in the darkness, though the darkness comprehendeth it not."

The pestilence that once walked in darkness and the destruction that once wasted at noonday, now destroy no more, because the hand of a Jenner, a Pasteur, or a Koch has said to destroying disease, as was said by a Mightier one of old to the engulfing sea, "thus far and no farther." The destructive force of devastating nature becomes impotent of harm, and the fears of threatened and trembling humanity are allayed. Few of the thousands of human beings rescued from former peril of small-pox ever think of the inestimable service rendered them by Jenner and vaccination, as the thousands yet to be saved from terrible death, "in consumption's ghastly form," or in cholera's fatal collapse, will in the years to come give not much thought to the mysterious salvation of Liebrecht and his cantharadizin or the inestimable researches of Koch; nor will it

think of the millions of deaths saved through other bacteriological researches and the numberless hygienic, health-saving, death-resisting discoveries freely given to the world by the medical profession of the nineteenth century. How little does the world at large think, in its wild chasing after folly as it flies, after wealth and fame, honor and glory, which so elude the pursuer and throw him into the hands of the physician, of the restless and myriad-peopled world about it, which has been conquered to health since the memorable, original bacteriological discovery of Leuenbroeck, about two centuries ago, so that man now lives where he formerly died, through applied science and the labors of the medical profession. And while the conflict goes on, the physician stands sentinel for mankind, fighting his battles for him against the destroyer of his peace and the things that threaten his health and life. Yet how little does the rescued world now think of its obligations to the medical profession for its escape from the fatal dangers of malaria, and the horrible ravages of small-pox, cholera, etc. The world has almost forgotten how deadly the Pontine marshes were in the time of the Cæsars, and how comparatively safe they are now through the advances of hygienic, prophylactic, and therapeutic science.

The medical profession is humanity's earthly human providence. It watches over man, unappreciated and unthanked, often, in his hours of wakefulness and while he sleeps, from his cradle to his grave, and wards off threatened dangers unseen by others, and as in regard to that supreme Providence who rules over all, man often gives the doctor and his vigilant work for his welfare a thought only in his last hours when he is too feeble to think of anything else and, alas, sometimes when it is too late for his physical, as it may be for his spiritual, salvation. Glorious profession! practiced in the life of Christ and His loving disciple, Luke, the good physician.

NON-POLITICAL INTERFERENCE WITH PUBLIC MEDICAL CHARITIES.

The medical profession champions the cause of the weak and the afflicted. It is fitting, therefore, that I should close this address with a word for the world's helpless wards who cannot speak for themselves.

To the victors may belong the spoils of political conflict, but where the spoils are human victims, minds dethroned and sacrificed to medical incompetency and party policy, we who are the professional descendants of those who brought these unfortunates out of the cruel bondage and neglect of a past inhumanity and superstition towards them, should secure for them the proper medical, as well as custodial care, which their disease demands in lieu of their broken chains and filthy, neglected dungeons.

Many of them, even in our almshouse and county asylums, have fallen from high mental estates, even higher places than those held by some who hold in the hollow of their hands their destinies, and their pitiable helplessness mutely pleads with our consciences to extend them sympathy and aid. We should endeavor to so influence public opinion and to so use our ballots, that parties and politicians so politic and inhuman as to sacrifice the mentally and physically maimed, or ill, in public hospitals and other of our eleemosynary institutions whom it is our special duty, under Providence, to guard, shall know the profession's indignation and feel its power.

The ordinary physician requires several years of training in these institutions added to his general professional knowledge and experience, to fit him for the proper understanding and care of the insane. To turn him out at this time, as is often done, and put in a novice, is not only a wrong to him who has given up his private business, expecting a permanent municipal position, but it is a crime against humanity against which science, experience and every instinct of human charity protests.

It would not damage the interests of parties to apply rules of Civil Service reform and fly the non-combatant flag over our State and city hospitals, especially for the insane, remembering that the mentally maimed who have fallen in life's conflict, are entitled to something more than to be tenderly carried from the field on a stretcher to a place of shelter. They should have their wounds skillfully treated and they should be restored, if possible, again to duty. This, a sense of duty and every consideration of sound public policy, prompts us to so do and to demand.

THE DOCTOR IN POLITICS.

One other subject, briefly, and I close. The doctor has too long held aloof from affairs of State. Result—our greatest names in medical history ignored if not forgotten; our highest interests and those of the people neglected and unappreciated. Benjamin Rush, great in his day and greater now, signer of the Declaration, Surgeon-General of the American army during its struggle for the life it gave the nation, author of immortal fame in medicine and a practitioner of skill and wonderful expediency in the grave emergency of a British embargo which saved the Continental Volunteers much suffering, has yet no monument to his memory. McDowell and Sims, too, and Jackson, who if ever military hero or civil statesman deserved to be so remembered by a grateful people, should long since have been commemorated in bronze or marble at the nation's capitol. They would have been if our best medical men, imitating the great Virchow

and others abroad, had taken part in the legislation of this country. The medical staff of the army and navy, too, would have had the higher rank which they deserve.

A PHYSICIAN IN THE CABINET.

Had we thus looked to our interests the President's Cabinet would long since have been represented by one member of the profession, as the law, agriculture, finance, etc., are. We should have had the Medical Minister of Public Health, for which the American Medical Association is just now pleading, much to the profit of the people in the saving of the public health and of innumerable lives and to the honor of the profession, which, above all other callings, has been the friend and benefactor of mankind, giving to humanity one of its greatest blessings and to the world many of its greatest and best men, whatever the world may say to the contrary—men who, like Hippocrates, destroyed the most fatal of the world's delusions and proved that law and not the caprice of the gods governed Nature's rule over the morbid processes, or like Vesalius, who dared and did for mankind more than ever warrior or valiant on the field of battle—Nature's uncrowned noblemen, who may yet live in the hearts of some unlaureled, even as the memory of Harvey and Jenner and Jackson and McDowell and hosts of others here unnamed, are not yet fully appreciated by the world at large. But their deeds will shine brighter and brighter as the world comes to know them and fully realize as we do their incomparable benefactions, their unsurpassed greatness and their unequaled heroism.

ORIGINAL ARTICLES.

MEDICAMENTS.

Read in the Section of Materia Medica and Pharmacy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 5-8, 1891.

BY EDGAR L. PATCH, M.D.,
OF BOSTON, MASS.

After considering many subjects fitting to be brought before this Association, we selected the above as one permitting us to group a few random thoughts, serving perhaps to provoke discussion, from which may come something of value.

Comparing the complex pharmacy of to-day, with its alkaloids, glucosides, neutral principles, and synthetic compounds; its coated pills, lozenges, tablets, triturate tablets, capsules and cachets, with that of the near past, manipulating the crude material into infusions, decoctions, tinctures, powders and pills, we are sometimes led to call a halt and ask if scientific medication is any nearer, and inquire if disease is held more

in abeyance by this great array of rare and expensive remedies.

As pharmacists we may not be able to discuss why quinine at twenty-five cents an ounce cannot do all the work it performed when two dollars an ounce, nor why it is replaced by a patented product, antipyrin, of five times the present cost of the alkaloid.

We cannot tell why antifebrin at four dollars a pound shall have a different action from the same chemical product called acetanilid, costing one dollar a pound.

We can only press forward in the rush, and secure as early as possible the new medical novelty, that the commercial enterprise of the manufacturer provides, and the bitterness of human distress, with the eagerness of the physician to employ every adjunct to power of relief, creates a demand for.

The question is often asked, "Is not the manufacturer with his pseudo proprietary or patent remedies an unmitigated evil?"

The physician, distressed by the demand upon his time for the consideration of the claims of legions of new remedies:—chagrined by learning that he has been giving chlorides and sulphates and attributing their effects to phosphates:—mortified at being misled into prescribing nostrums that in composition bear no relation to their schedule of contents, declares war.

The pharmacist, annoyed at being forced to invest his capital at a loss, purchasing an original package for a single demand, or adding to his stock the tenth novelty or synthetic of similar intention and untried value, into which enters none of his learning, originality or skill, becomes disgusted.

Both appear to be planning a "coup de main" when the actual merit of some such compound and the great and permanent good it performs opens up a new era of tolerance.

Will it ever be possible to establish a joint commission of physicians and pharmacists to examine and report upon these products?

Each remedy to be investigated, and, as far as chemistry can determine it, first be proven to be true to name and assumed composition, then to be tested for therapeutic value by those perfectly capable of giving it its right estimate.

The blame of blind medication by physicians, the needless use of improper remedies, and faulty self-treatment by an uneducated public, is chargeable to physicians and pharmacists alike.

The one profession prescribes and teaches the public to call for the remedies and the other too often recommends them. Ignoring this class of medicaments, is it possible to secure anything like uniformity in medication? Has there been a decided advance in this direction? Each new class of preparations is supposed to further progress. How far this may be true let us consider.

Formerly great divergence was caused by the lack of a national standard, but now that we have one of the best pharmacopœias extant do we have constancy in composition and activity of remedies? Unfortunately many physicians and some pharmacists ignore the pharmacopœia and govern their course by a dispensatory that may or may not antedate the standard, and is not intelligently compared with it.

Again, the great variation in crude material, and the modification by manipulation prevent uniformity.

The class of fluid extracts was supposed to supply uniform, concentrated solutions, permitting small dosage, with less alcohol interference than tinctures, and free from the ferment changes of infusions and decoctions.

Assuming that the menstruum was alike for the same drug, faulty storage in too damp or too dry a situation might alter the strength of the drug from 10 to 40 per cent. by variation in moisture alone. This moisture diluting the alcoholic solvent affects its power of solution. By variation of 20 degrees F. in temperature at time of percolation, 25 per cent. difference in strength may occur. In addition to this, note the facts that the call has been urgent to modify menstrua so that the fluid extract may be used for making tinctures and syrups, and you perceive that many of this class are not fluid extracts in any accepted sense of the term.

The use of this class for making infusions and decoctions is of course a radical departure from right practice in nearly all cases. Water dissolves gums, sugar, extractives, etc., that are largely rejected by alcoholic menstrua, while the latter dissolve volatile oil and resin combinations, tannin combinations, alkaloids, etc., that are insoluble in water, and preclude the miscibility of such fluid extracts with aqueous vehicles.

Competition and storing to complete precipitation have further modified strength in drug and menstrua, until physicians testify that they find one pharmacist's tincture as strong as another's fluid extract and that tinctures, infusions and decoctions are often nearly valueless.

To illustrate this point we present five samples of fl. ext. belladonna. The official is made from the root with alcohol of 91 per cent. weight strength as menstruum. It averages to contain 8 per cent. of extractive and 83.7 per cent. alcohol by weight. No. 1, Ext. 5.6 per cent., Alc. 87.12 per cent. No. 2, Ext. 7 per cent., Alc. 83.62 per cent. No. 3, Ext. 16 per cent., Alc. 57.12 per cent. No. 4, Ext. 16.3 per cent., Alc. 48.7 per cent. No. 5, Ext. 15 per cent., Alc. 47.8 per cent. (Examined by E. E. Bickford, Ph. G., Mass. Col. of Pharm.)

You will observe that those containing least alcohol are densest and darkest in color. This is due to excess of water and solution of more

extractive and coloring matter. Should a prescription be written calling for this fluid extract and camphor or other volatile oil, as in the official Lin. Belladonna, these fluid extracts will not dissolve them.

We also show five samples of fl. ext. of aromatic powder. No. 1, Ext. 10 per cent., Alc. 60.6 per cent. No. 2, Repercolation, Ext. 10 per cent., Alc. 61 per cent. No. 3, Ext. 7.7 per cent., Alc. 64 per cent. No. 4, Ext. 6.1 per cent., Alc. 54 per cent. No. 5, Ext. 2.3 per cent., Alc. 45 per cent.

Physical inspection of these samples shows their great variation.

To show the character of infusions and decoctions made from standard fluid extracts, we present Inf. Buchu, Infus. Capsica, Infus. Pruni Virg., Dec. Cinchonæ Flavæ and Dec. Uvæ Ursi.

Observe their unsightly appearance and note that filtration removes much of their activity.

This line of illustrations might be extended to great length, but these presented should be sufficient.

MEDICATION BY PILLS.

A pill should be a mass of medicinal matter spherical or ovoid in form, of such consistence as to maintain its shape and yet be readily soluble or disintegrated in the fluids of the stomach.

If properly made, no doubt a fresh pill is always better than an old one. It is not in our province to tell what the physician shall order in pill form, but it is a great pity that more discrimination is not used in this direction, and it may in some cases be better for the patient that the pill is old and does not act. The superiority of finish and greater palatableness of coated pills and the delay incident to waiting for freshly made pills has opened the way to the introduction of those of manufacturers. We are not prepared to say that this is against uniformity. If you examine the thirty samples of pills put up extemporaneously, you will find a wonderful variation in the products obtained by the same prescriptions.

If you compare the thirty specimens from the manufacturers, you find a great range of style.

Note the citrate of iron and quinine pills, green, red and black. The official salt is red.

Note the A. S. & B. pills. Mostly black. The mass is greenish, but the doctor says the black pill is more active, and so the patient must have a painted pill. Note the yellow quinine pills. This is simply due to age. Quinine, cinchonidine and many other masses change in this way.

Note the five kinds of Bland's pills.

The common formula calls for equal weights of ferrous sulphate and potassic carbonate. This gives a large excess of potassic carbonate and an alkaline pill. Such pills gelatine coated, the coating dulls. Note then this glossy pill with a

mass nearly neutral, practically Vallet's mass with potassic sulphate added. Notice this beautiful pill, type of a line of "*gelatine-coated*" (?) goods "*without pin-hole*." An hour of maceration in water does not expand any gelatine or act upon the pill. Cutting with a pen-knife reveals a *sugar coating*. Alcohol removes its glossy coating of *resinous matter*. Note how readily the iodide of iron pills decompose.

Yet, despite the fact that the call for style and durability has led to the introduction of wonderful "*improvements*" (?) in pill making, it is doubtless true that manufactured pills average being nearer to their assumed composition than will the same number and variety obtained at the dispensing counter.

TABLET MEDICATION.

As a supposed advance upon pills, compressed tablets were introduced. The general claims were—"made from dry powder, without excipient and much more soluble than coated or old stock pills."

These claims are in a measure fallacious.

Crystalline salts can often be compressed without the addition of foreign matter, but powdered drugs and such chemical products as sodium salicylate, reduced iron, quinine sulphate, etc., must be moistened with some excipient, granulated and dried, before compression.

To prevent the adhesion of many of these masses to the dies, some agent must be employed for lubrication and this diminishes the solubility.

Brief consideration will show that a compressed tablet, offering much less surface to the action of the solvent than does the original material in powder form, will always be less soluble.

If the reverse occurs the tablet cannot be true to its label. To illustrate. We have some quinine bisulphate, some tablets of the same made by compression without any addition, and samples of commercial products.

You observe that the salt dissolves by much agitation in the quantity of water used; the correct tablet much slower, but, presto, the commercial tablet falls apart and dissolves quicker than the original salt. The bubbles of gas evolved during this change hint at the character of this "*improvement*."

Note how quickly this sodium salicylate dissolves. Observe the difficulty in dissolving the tablets. Press the tablets between the fingers and note the greasy feeling. Assay and find .003 of grease in each tablet. This gives them a fine finish and tends to prevent change, and the fact that thousands of pounds are prescribed may show that their slow solubility does not impair their physiological action.

The physician wants a tasteless tablet. Note how it is arrived at in the quinine and chocolate tablets before you. The sweetest, most delicious,

can be taken ad libitum. One physician personally used the greater part of an entire package without action.

Note the variation in these alkaline antiseptic tablets. All have the same formula. Note that some make a practically clear solution. Yet if the quantity of eucalyptol, thymol and menthol claimed, was in each tablet, it would be physically impossible. But the physician may reject the stronger tablet, true to its label, and give preference to the weaker, fancying the manufacturer has some sleight of hand to overcome natural law and take his rivals at disadvantage.

Yet this form of medication has presented to the physician many valuable remedies in convenient form. It is only necessary to call attention to these peculiarities of method that you may intelligently give each its due measure of merit.

TRITURATE TABLETS.

The suggestion of Dr. Fuller that active medicinal agents be thoroughly triturated with milk sugar, the mass dampened and formed into tablets by pressing in hard-rubber molds, furnishing a friable, readily soluble product of accurate dosage, has met with the approval of many physicians.

For hypodermic use and for the great majority of remedies that can be administered in small dose, this form is undoubtedly an advance over the pill or compressed tablet triturate.

If the minimum amount of moisture is used, the change incident to molding and drying is very slight. It is a misfortune, however, that many agents are ordered in this form that are not at all adapted to it; as large doses of solid extracts, and salts that suffer decomposition when mixed and moistened.

CAPSULES.

Gelatine capsules have been recommended as furnishing a means of administering nauseous remedies in condition ready for rapid assimilation.

The intention is sometimes interfered with by the druggist first forming a pill mass of the material and placing this in the capsule, instead of using the dry powder. The moisture of such a mass, if excessive, may soften the capsule, consequently a hard mass is often used.

We have found great variation in the size of capsule employed for the same prescription, and failure to instruct the patient as to the character of the container, has brought about some very amusing episodes.

WAFERS AND CACHETS.

The wafer, a disk of flour and gum, is well adapted for use in administering disagreeable powders. A common difficulty in using them consists in moistening too much before folding,

producing a soft unsightly mass. The seal or cachet, a special form of wafer, is preferable. The edges only are moistened and two sealed together with the powder between. We believe an improvement over the present hard pills would be the furnishing of these cachets in shape and size to take pill mass of rather soft consistence, but not soft enough to impair the cachet.

ELIXIRS.

This class of medicaments has come to stay. It is a radical departure from the theory of medication by small dosage, using active fluid extracts, resin, resinoids, alkaloids, etc. These pleasantly flavored, mildly alcoholic solutions, seem to be popular in proportion as they are agreeable in taste, and to meet this requirement they are sometimes divested of much medicinal activity.

One illustration, the examination of eight samples of elixir of three phosphates, will suffice.

RESULTS OF ASSAYS.

No.	Quinine as Sulph.	in each fld.,	.730 gr.	Strych.	.017 gr.
1.	"	"	"	"	"

6.	"	"	"	"	"
7.	"	"	"	"	"
8.	"	"	"	"	"

The last two contained chloride of iron instead of phosphate of pyrophosphate. This innovation was undoubtedly made to furnish a permanent elixir miscible with water. The others, made with phosphate and pyrophosphate of iron, inevitably grow dark and form a cloudy solution when mixed with water.

We present five samples of so called elixir of three phosphates, and five of elixir gentian with tincture chloride of iron.

This running fire on preparations serves to show the variation in medication arising from

manipulation alone. Add to this the variation in crude material and we see that accurate and uniform medication is far away in the future. Yet there is a cry from the Egypt of dimness for more light through the window of standardization.

Can this be practically arrived at?

We claim that no ordinary chemist, well versed in the theory and practice of analysis, is capable of obtaining reliable results with most assay processes now in use, without much previous practice with each method. Much less can the pharmacist, constantly interrupted with the other demands of his calling, perfect himself in many processes of assay. The errors arising from false standards so obtained would introduce an element of danger more serious than any yet mentioned. We take at random results obtained by different workers on the same samples of drugs, each assayer having quite the average ability and better than ordinary facilities for doing the work.

We might extend this illustration through many assays, but scrutiny of this brief table will disclose the point aimed at.

No.	1.	Drug.	Alkaloid.	Per Ct.	Drug.	Cantharidin.	Per Ct.	Free	Po. Opium	Morph.	Morph.

Will it not be dangerous to fix a standard for these potent drugs, unless with it we have a law that they shall be assayed by experienced men in State employ, at the points of distribution? Otherwise we may be left to a variation of 1,500 per cent. on account of a faulty assay!

If we have such assay and standard, the error in manipulation will be reduced to 50 per cent. as a maximum.

But if we have absolutely standard remedies, can we have *uniform medication*? Shall we not continue to hear of idiosyncrasy of patient, faulty diagnosis and prognosis, causing miscarriage of intention and application of medications?

Is not a desirable line of advance that of better training of the medical student in the direction of practical materia medica and pharmacy?

Is not the course of instruction in many medical colleges deficient in this respect?

Would not pharmacists be more intelligent coadjutors of physicians if the course of instruction in pharmacy colleges included more attention to therapeutics?

THE PREVENTION OF MORPHINISM. A THERAPEUTIC REVOLUTION: CODEINE AND NARCEINE, VICE MORPHINE.

*Read before the Section of Materia Medica and Pharmacy, at the
Forty-second Annual Meeting of the American Medical
Association, Washington, D. C., May 6, 1891.*

BY J. B. MATTISON, M.D.,
OF BROOKLYN, N. Y.

The prevention of disease ranks higher than its cure, and he who essays the rôle of benefactor along this line, deserves well of his fellows, be results success or reverse. I shall presume to make an effort at filling that rôle to-day; shall try to command your attention by enlisting interest in what promises to remove, very largely, a stigma that has rested long and weightily on the healing art, and by wiping out this blot on the scutcheon, secure favor by virtue of not only an advance so decided as to mark a new era in therapeutics, but, above all, by lessening in large degree the main factor in a disease that spares neither sex, state nor condition, and which, sad to say, claims for its victims more of our confrères than the world will ever know.

Pain and insomnia, with the use and abuse of morphia for their relief, are the leading twin causes of the morphine disease. Quite apart, however, is a peculiar power, *per se*, in this drug that makes it, so often, a bane after blessing—a suareful influence than which a stronger, save one, does not exist, and which carries with it, too often, degradation and death. It goes then, without saying, that if one can offer that which

will bring ease, and win the “sweet restorer” *without* this harmful sequence, he will entitle himself to the plaudit of profession and public, by averting a danger that threatens the well-being of the person and society at large. Such, in much measure, I think we have in codeine and narceine. The former has long been used, to a minor extent, the latter is rare. Opinion has varied as to their value, but my experience with each, in a field special, unique, and to some extent unequaled, has brought with it a belief in their virtue along painful, insomnic lines, and a confidence so pronounced that I bespeak for them your careful, practical consideration.

I am not willing to say there can be no codeinism or narceinism, despite the statement of Fischer that “tolerance and habituation analogous to morphine, are not caused by codeine,” but I do assert that the snaring, seductive power of codeine is vastly less than that of morphia and that this one negative power for harm alone should secure for it a larger share of professional confidence and field for remedial work than it has hitherto had. Nor am I ready to say that codeine has a value, aside from its anodyne, equal to morphia in inflammatory conditions, nor that it has like power as a stimulant. To neither of these does my argument apply, but solely to its use in painful, agryptic conditions, apart from temperature rise or cardiac decline.

Codeine was discovered in 1832, by Robiquet, who wrote in its favor, and two years later, Barbier and Bertha, after a series of careful experiments, claimed its special tendency towards the sympathetic system. These reports were confirmed but, like some other valuable drugs, digitalis, for instance, the merits of codeine were for many years in abeyance, and only within the last half decade has it come well to the front with a claim for doing good work too strong to be disregarded.

Foreign physicians, especially on the continent, have always led in the use of codeine, but the time is quite here for us to follow their good example, and I cannot now do better than to commend to your careful reading a valuable paper by Lauder Brunton, the *British Medical Journal*, June 9, 1888. Dr. Brunton lauds it highly, declaring he is satisfied that, to use his exact language: “it has a powerful action in allaying abdominal pain.” He cites various painful conditions in which it has served him and his colleagues well, and closing his paper remarks that he “thinks it not improbable that codeine, which has almost fallen into disuse as an anodyne, will again come into vogue.” I endorse every word of Dr. Brunton’s, and venture the belief that we are on the eve of a larger use of codeine, in pain and insomnia, than the American profession has yet known.

I will not weary you with stating the various

morbid conditions that codeine will control. Its province is more or less relief of any and every pain, but it is especially adapted, by virtue of its non-tolerant power, to neuralgic disorders which stand so largely and so closely in genetic relation to the abuse of morphine; and, in general, to any and all long-continued pain. Even in incurably painful conditions it is often better than morphia, bringing ease without the unpleasant gastric and other sequelæ of the latter drug.

The hypnotic action of codiene is also distinct and decided, and may be quite apart from any analgesic need. It is a reliable soporific, though sometimes acting more slowly, yet, without the dulness or headache often sequeling morphine.

A great gain in using codiene vice morphine as an anodyne and hypnotic is that it lacks that inexplicable influence of the latter—before noted—in making itself felt, apart from relief of pain, and so creating a morbid condition, a so-called "craving," that will not be denied. I confess to you, gentlemen, that though I have been studying opium and opium habitués for more than twenty years, I do not fully understand it, but am more and more impressed by this peculiar power with every case that comes under my care.

Another point in favor of codiene is the non-need of increasing the dose on long usage. The reverse so often obtains with morphia that it marks one of the distressing features attending habitual use; growing by what it feeds on, it steadily adds to the hapless lot of those who from force of conditions beyond control, find themselves compelled to mind an imperious power they are helpless to resist.

To get good results from codiene it is essential to have it pure. Such is supplied by Merck, of Darmstadt and New York. The sulphate and phosphate—the first by mouth, and the other for subcutaneous use—are the most eligible. The latter is freely soluble—more so than morphia, my usual solution being six grains to the drachm. It should be freshly made; bitter almond water tends to preserve it; I have never noted local harm.

The dose required is larger than morphia. Fischer says triple; Bartholow four times. Fischer has written more largely of codeine—detailing several years experience—than any other foreign physician, and to him is mainly due my extensive use of the drug. I commend to you his papers in the German medical press of 1888. An initial dose of one-half grain by mouth, or one-quarter to one-half grain by skin is safe, and may be repeated and increased as required.

Narceine, though so little used, is a soporific of value. It is not an anodyne. Failure will result if pain be present. The dose should be double that of morphia. The hydrochlorate—Merck—admits of hypodermic use.

Gentlemen, you have my paper. It is a plea

for less morphine—more codeine. The usually accepted statement that its anodyne and hypnotic action is weak and uncertain, is wrong. It has a constant and well marked effect as an analgesic and soporific, without unpleasant secondary symptoms—nausea, headache, and general malaise so common with morphia. I urge you to use it, and especially do I commend it to the junior members of the profession, who too often are enthused with that modern mischief maker, hypodermic morphia, and have not yet gained the wisdom given their fathers, whose experience has led them to discard—increasingly often, I am glad to say—a power so potent for ill. I speak feelingly on this subject, gentlemen, for my professional work for many years has brought me in daily contact with those—mostly our own guild—whose lives have been blighted by morphia.

The easing of pain ranks next to the saving of life, and when in doing such noble work, we do it without entailing a bondage binding, it may be, for life, the millenium will be nearer than now.

Brooklyn avenue, Brooklyn.

SOME NOTES AND REFLECTIONS ON OLD REMEDIES.

Read by title in the Section of Materia Medica and Pharmacy, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May 6, 1897.

BY L. E. SAYRE, PH.G.,

UNIVERSITY OF KANSAS.

It is a truism to every student of medicine and pharmacy that there is little that is absolute in remedies. Specifics exist in theory rather than in fact. But we may classify and safely divide all remedies, in point of time, into three classes: First, those which have come to us from very ancient date, which have been used from time immemorial, whose introduction into the materia medica dates back to the earliest history. Second, those of more recent date, but which are properly called old, those which have stood the test of criticism from all portions of the medical world—the old and tried remedies. Third, those which we very properly call "new remedies"—the new and the untried remedies. This classification, it is true, is unscientific, but is used simply to give proper perspective to my subject. It is my purpose to dwell upon the second class, the old remedies, whose efficiency has been well tried, and whose value is unquestioned.

We are living in an age of new remedies. Every medical periodical contains notices of their efficiency and power, and peculiar adaptability. They are becoming so popular that one outside of the profession might well suppose that a new pharmacopœia was at hand, which will, if not entirely obliterate the old remedies, at least over-

shadow them. I do not wish to be understood as speaking slightly of the new remedies, but it seems natural that I should revert to the old, having devoted so much time in their study.

One can scarcely glance over the pages of the medical literature of the past half century without becoming impressed with the significant suggestion that a vast amount of empirical knowledge constitutes a great part of medical science taken as a whole. Crude drugs have come and gone, clinical observations upon them have been scored by the hundreds, and very many of these have left their impress in black and white, to be sure, in the pamphlets and volumes in which they are printed, but at present are happily reposing in the limbo of forgetfulness. The physician of to-day is heir to all this good, bad and indifferent empirical observation and information. This may be cause for much gratitude and pride, but one cannot resist the suggestion that the present evolutionary period of medical science has been at the expense of "putting a good deal of medicine of which we know nothing into bodies of which we know little." It is related of the oculist Wenzel that he had to spoil a hatful of eyes before he learned how to operate successfully on cataract. The application is too painfully obvious to need further comment. True to evolutionary theory, let us hope that all the empiricism of the past has had the practical result of benefit to science as well as society.

If one studies the medical literature appearing to-day he can clearly see that empirical ideas and practice are gradually giving place to rational methods and treatment, and, whilst many of the old remedies are continued, they are to serve a different purpose—are to be viewed from a different standpoint than that of even the few years preceding the present. Therapeutics, chemistry and pharmacy (which is largely chemistry applied to medicine) are growing side by side and are gradually changing the aspect that these remedies once had. Their application is becoming magnified and exalted, so to speak. The therapeutic uses of these remedies are to have their origin in their physiological action. Physiological action is to be explained and even anticipated or predicted by chemistry, and this action definitely made possible by the art of pharmacy.

Interspersed among the new remedies of to day we find the familiar forms of these old ones. The process of elimination will doubtless go on in the future as it has in the past, but from the present outlook it is fair to presume that such crude drugs as ipecac, rhubarb, cinchona, nux vomica, digitalis, hyoscyamus and a host of other like vegetable drugs, will continue. The same may be said of many of the inorganic substances as found in the salts of the alkalis, alkaline earths and metallic substances, their chlorides, bromides

and iodides; their carbonates and sulphates; their citrates and acetates, etc. Despite the theories concerning disease and the development of synthetic chemistry, which would if it could combine the veritable antagonist to each particular disease within the molecular spaces of the "benzene ring" or the "carbon chain"—despite all this, it is fairly probable that the old remedies will live to do battle with the microbes (and their poisonous products) of the twentieth century.

But these old remedies are to take a higher place than heretofore. We are to know more about them than in the days of polypharmacy and polytherapy. We are more clearly to understand their intrinsic value. That the medical profession as a whole is every day gaining more sharply defined descriptions (chemical, therapeutical, etc.,) regarding them one can readily see by glancing at the current medical and pharmaceutical literature. Since the study of alkaloidal constituents and active principles in vegetable drugs a flood of light has been poured in upon the therapeutic value and action of these; the relation of chemical composition and therapeutic action has been fully established. Aconite, belladonna and ipecac are valuable in proportion to the amount of alkaloid they contain, and so we may say of a host of other drugs. Some drugs are for certain purposes best administered in the natural combination, for reasons we are to-day better able to give. Rhubarb doubtless owes its beneficial action in catarrh of the stomach, indigestion, etc., to chrysophanic acid, one of its prominent constituents, a powerful antiseptic. In such cases is rhubarb especially valuable, because, when the drug reaches the stomach, the chrysophanic acid is separated in the nascent condition and consequently in the condition in which it is the most active. This little bit of the chemistry of rhubarb emphasizes the fact that when this drug is administered internally this constituent should be present in its integrity. To the pharmacist as well as the physician this information is equally of importance, for to him it shows that in his preparations of this drug this constituent should be retained. The adoption and use as therapeutic agents of the alkaloids, glucosides, etc., (many of the so-called new remedies) is an exemplification of the principle of advancement above stated. It has been but a few years since there was a contempt for these active principles existing in the medical profession. Quoting from a little volume (a translation) written by Dr. Robley Dungleson in 1824, he says: "There exists an objection to the principle of thus isolating and concentrating the active parts of our remedies. Perhaps every practitioner feels that medical substances are more efficacious as they are presented to us combined by the hand of Nature, than when their active part is isolated and recombined by the hand of man. Thus we

are all inclined to give our remedies in substance, as it is called, rather than as prepared in a more convenient form by the chemist or druggist; and we are only deterred from using these natural products by the greater bulk, and other inconvenient properties of them, as compared with the more artificial preparations of them."

"If we take these isolated and concentrated remedies as they are, we find that at least many of them are endowed with peculiar and powerful properties; and as nobody can deny that it is far more convenient to use remedies which are in small bulk, we have to take such remedies as if they were simple remedies, and investigate their properties as we would those of any natural production." He quotes the language of some of the profession of that day as regards the view taken of the isolated principles. He says: "Ay! here they come, one after another, vaunted to the skies for properties which sober investigation shows not to belong to them; we shall soon see them laid on the shelf, until they are again held up to the world as prodigies by some future enthusiastic searchers after novelty." In the day when these lines were written quinine, strychnine, emetine and brucine were considered novelties. In the same book Dr. Dugleson defends the use of such drugs as digitalis, prussic acid, colchicum, etc., against the popular current of thought. Only a little "looking backward" is necessary to prove the proposition that we are gaining more sharply defined ideas concerning the old remedies.

We are very much indebted to the labors of pharmaceutical chemistry for the recent studies into some minuter points concerning the nature of some of these old remedies. And I may say in passing it has been largely a labor of love. I have not space nor time to amplify upon this point. I will, however, to illustrate, give one example. I will refer to the study of the constituents of the narcotic leaves as represented by the solanaceous plants, belladonna, stramonium and hyoscyamus. In presenting this I will summarize what has been done in the direction of the chemistry of these drugs. This can best be done by reference to the alkaloidal constituents. Researches prove that the three mydriatic alkaloids, atropine, hyoscyamine, and hyoscyne are contained as follows: Atropine in atropa belladonna and datura stramonium. Hyoscyamine in atropa belladonna, datur-stramonium and hyoscyamus niger. "Heavy daturine" is identical with atropine; "light daturine" and "light atropine" are identical with hyoscyamine. Duboisine is nearly pure hyoscyne. Pure atropine and pure hyoscyamine as well as hyosine are isomeric alkaloid, but possess different chemical and physical properties. Therapeutically hyosine possesses about five times the calmative power of atropine or hyoscyamine. Tropine (a product

from hyoscyne) and tropic acid may be recombined under certain conditions to form atropine. The union of tropine with amygdalic acid is homatropine, or oxytoluyltropine. This body will, like atropine, form salts with acids. Thus we have the valuable mydriatic hydrobromate of homatropine. This is only one of the many interesting results of chemical study bearing upon the future of the old remedies.

At the close of their term of service the committee of revision of the 1880 Pharmacopœia issued a volume of criticisms upon the old United States Pharmacopœia. It is a volume of some 350 pages, large octavo of closely printed material. The criticisms are paragraphic, brief, and concise. It is a noteworthy fact that nearly all of these criticisms are upon the old remedies. This shows us conclusively that in spite of the prominence which has been given to the new remedies, the old ones are receiving more careful attention at the hands of the pharmacists and therapists than ever before. Were these brief notes or criticisms expanded so as to include the text of the many articles and monographs referred to, at least 12 volumes of equal size would be made. A careful study of all this literature must convince and impress any one with the significant fact that in the past decade a vast amount of work (in the laboratory and in the study) has been done upon these. My attention, as one of the members of the committee of Revision, has been especially directed to the salts of lime, copper and iron. It is plainly evident to me that, in order to bring these salts up to the present demands, a vast amount of work is required. This involves the verification of the criticisms in the laboratory, the elimination of the old text improved upon, and the addition of new material. The work in one particular salt (hypophosphite of lime) requires several days of spare time. This salt in the future should be a standardized salt, so to speak. To this end Mr. Moerck of the Philadelphia College of Pharmacy, has contributed pages of chemical literature (See *Amer. Jour. Pharm.*, 1889, pp. 329 to 332; 386; 391). This is but one item among the many hundreds of inorganic salts and their preparations, thus to be treated and brought forward to date.

The hypophosphites of each of the other bases require special analytical treatment, but they are all to be made up to a certain well defined standard. In a general way it may be said that all of the inorganic salts are to be more sharply defined by chemical tests, and the quantitative tests are to be made more rigid and severe. Wherever possible, improvement and advance is to be made. For example, chlorinated lime; the best samples of this salt formerly assayed no more than 25 per cent. of chlorine, now, the quantitative test for this salt will demand at least 30 per cent. of this

element. No quantitative test for sulphate of copper is present in the Pharmacopœia, but a demand exists for a test which will betray a trace of impurity.

At the same time more practical and easy methods for making these tests have been studied out and the purpose is by these improved methods to make "testing" more popular even among those who are away from the centers of supply of chemical apparatus. Wherever possible volumetric tests are to be substituted for the more difficult gravimetric tests. The test tube is to be made to do more duty—made to accomplish more than it has in the past.

All this points to a state of progressiveness and indicates that these old remedies are, from a pharmaceutical point of view at least, to be viewed with additional interest. The spirit of precision and accuracy is in the air, as it were; this spirit doubtless has been caught from the sister science of medicine, for it is worthy of notice that therapeutics is advancing along the same lines of precision. This one science shows us at least most markedly that we are advancing beyond the domain of empiricism.

Medical literature, as has been suggested, has been prolific in its contributions to the study of remedial agents; the therapeutic work is even more interesting and important than the pharmaceutical, and, I may add, a more important factor in changing the present aspect of these old remedies. Unfortunately this literature is not as accessible as it might be to those who are interested in the revision of the Pharmacopœia. Perhaps it is not necessary that it should be, but I venture the remark the pharmacopœial revision must suffer in proportion to the indifference of the therapist in this important work. A true scientific spirit should bring together the therapist and pharmacist; the bearing this would have upon medical progress cannot be estimated. The discussion of this question, bearing as it does on the subject of old remedies, can better be left to others. I will, however, in closing merely touch upon it, using the words of Dr. E. R. Squibb (*Ephemeris*, 1889, p. 1249). After expressing his regrets that the medical profession indifferently treats the subject of pharmacopœial revision, he says: "The pharmaceutical profession, which has a more direct pecuniary interest in the subject, has continually increased in activity, discussing the subject in its organizations, and carefully selecting its very best men for its delegates to the convention." . . . This being the case he points out that these pharmacists are likely "to lead the convention" which considers the subject of revision and "the revision would show wherever there was contrariety of interests that pharmacy would prevail." Dr. Squibb kindly says in another article that "while pharmacists have been fully awake and recognized

their opportunity, they have not taken advantage of this unsafe and unwise drift." "The true interests of scientific medicine and pharmacy are, of course, absolutely the same, but the interest as they exist in practice, are not always the same. And, when they are not, those of medicine should always prevail, because their relation to the sick—the object of both—is nearer and more direct. Neither can do well without the other, but the one is much closer to the issues of life and death than the other, and cannot afford to trust these issues to a more distant dependence, which must always be more largely commercial or mercantile. The Pharmacopœia is equally the reliance, the guide, and the authority of both, but cannot wisely or safely be entrusted to the control of either." But the consideration of this question may be considered remote to the interests of medicine. Be this as it may, I have thought it might be suggestive and interesting, as well, to those for whom this paper is written.

SECTION XII, ON MATERIA MEDICA AND PHARMACY.

The Section on Materia Medica and Pharmacy of the American Medical Association met in Grand Army Hall on the afternoons of May 5, 6 and 7, Frank Woodbury, M.D., of Philadelphia, Pa., chairman. H. G. Ewing, M.D., of Nashville, Tenn., being absent, owing to sickness, F. E. Stewart, M.D., of Wilmington, Del., was elected secretary *pro tem*.

In addition to the members of the American Medical Association attending the Section, there was present a delegation from the American Pharmaceutical Association, including Joseph R. Remington, of the Philadelphia College of Pharmacy, chairman of the committee; Mr. Alfred Taylor, of Philadelphia, Pa., the venerable ex-president of the American Pharmaceutical Association, who had served on the committee for revising the United States Pharmacopœia since 1840; Prof. J. M. Maisch, of Philadelphia; Prof. Edgar L. Patch, of the Massachusetts College of Pharmacy, Mass.; Prof. Chas. T. P. Fennel, State chemist of Southern District, Cincinnati, Ohio; Mr. B. T. Fairchild and Prof. Bedford, of New York City. This delegation was welcomed appropriately by the chairman, and invited to take part in all the deliberations of the Section. A committee of the Section was formed to act on publication of papers and other business that might be referred to it, this committee consisting of the officers of the Section and Mr. Joseph P. Remington.

The following papers were read and discussed:

1. Pharmacopœial Nomenclature and the Latin of Prescriptions, by Prof. Joseph P. Remington,

of the Philadelphia College of Pharmacy, and member of the committee for revising the United States Pharmacopœia.

2. The Present Status of Materia Medica and Therapeutics, by J. W. C. Cuddy, M.D., of Baltimore, Md.

3. The Working Bulletin System: A Proposed Investigation of the Materia Medica of the World under the Auspices of the Government of the United States, by Frank E. Stewart, M.D., of Wilmington, Delaware, Demonstrator of Materia Medica and Pharmacy, Jefferson Medical College, Philadelphia.

4. The Future Chemist, by Prof. Chas. T. P. Fennel, of Cincinnati, State Chemist for the Southern District, Ohio.

5. Discussion on the United States Pharmacopœia, opened by Prof. Horatio C. Wood, M.D., etc., president of the Convention for the Revision of the United States Pharmacopœia. In this discussion participated Prof. Remington; Dr. Kirnan, of Chicago; Prof. Whelpley, of the St. Louis College of Pharmacy; Dr. Prentiss, of Washington; Prof. Patch, of the Massachusetts College of Pharmacy; Prof. Maisch, of the Philadelphia College of Pharmacy, member of the committee on revision, and permanent secretary of the American Pharmaceutical Association.

6. On the Relation of the Profession to Drugs Bearing a Trade Mark; with some Remarks in Regard to the Value of the Pharmacopœia to the Physician, by Hobart A. Hare, M.D., Professor of Materia Medica and Therapeutics in the Jefferson Medical College, Philadelphia.

7. Pharmacy for Medical Men, by Prof. P. W. Bedford, of New York City, member of the committee for revising the United States Pharmacopœia, etc.

8. American Pharmacy and Legislation, by H. P. Reynolds, Plainfield, N. J.

Read by title:

1. The Relations of Physicians and Pharmacists, by E. L. Boggs, M.D., Charleston, W. Va.

2. On the Official Sulphocarbolates, by Wm. F. Waugh, M.D., Philadelphia, Pa.

3. Potassium Chlorate; Its Toxic Effects, by G. A. Fackler, M.D., Cincinnati, Ohio.

4. Some Notes on Old Remedies, by Prof. L. E. Sayre, of the University of Kansas.

5. "Guests of This Hotel are Not Permitted to Use Iodoform," by I. N. Love, M.D., St. Louis, Mo.

A very important communication from Dr. Chas. Rice, of New York, chairman of the committee for revising the United States Pharmacopœia, was read, proposing a commission of physicians and pharmacists, to be appointed jointly by the American Medical Association and American Pharmaceutical Association, for the consideration of subjects, both scientific and ethical, of mutual interest to the professions of medicine

and pharmacy, and to report annually to the American Medical Association.

In the discussion upon this paper, it was generally conceded that the recommendation of Dr. Rice was timely and valuable, and that the formation of the Section on Materia Medica and Pharmacy was instigated by the same motives and opinions expressed in the communication, as by this means any subject of interest and importance to medicine and pharmacy could be reported promptly to each national association.

The papers having all been read, a business session was held.

The business committee of the Section reported:

1. That as the communication of Dr. Rice was also covered by Dr. Stewart's paper, suggesting the formation of a special society of physicians and pharmacists, and as the subject was a very important one, that the entire subject be referred back to the committee to bring before the Section again next year for further consideration.

2. It was recommended that the committee bring before the meeting next year a plan for more complete organization, with the view of facilitating business and developing the interest of members of the American Medical Association in the Section on Materia Medica and Pharmacy.

3. Resolved, that the Government of the United States be memorialized by the American Medical Association in favor of the plan proposed by Dr. F. E. Stewart, whereby the laboratories of the army, navy, marine hospital service, Smithsonian Institution, customs service, agricultural department, and other departments of the Government having charge of the analysis and identification of drugs, may be facilitated, and the results of their investigations made public, and that the information thus gathered may be disseminated for the general benefit of the professions of medicine and pharmacy.

The report of the committee was accepted and adopted, and the last resolution was directed to be referred to the general session of the American Medical Association for its consideration by the chairman of the Section.

An election for officers for the ensuing year resulted in the reelection of Dr. Woodbury as chairman, and for secretary Dr. H. M. Whelpley, of St. Louis, was unanimously chosen, the secretary casting the ballot of the meeting.

The Section then adjourned.

Signed: FRANK WOODBURY, M.D.,
F. E. STEWART, M.D., Chairman.
Secretary *pro tem*.

A MEDICAL CONSUL.—Dr. Jeremiah Coughlin, of Brooklyn, has been appointed by the President to be secretary of legation and consul-general of the United States at Bogotá.

THE ACTION OF THE TURKISH BATH IN DISEASE.

Read in the Section of Medicine and Physiology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY CHAS. H. SHEPARD, M.D.,
OF BROOKLYN, N. Y.

One year ago, I had the honor of presenting before this Association certain data regarding the treatment of rheumatism by the Turkish bath. Several gentlemen controverted the position taken in that paper, and now it will be my endeavor to give some facts substantiating what was then laid before you, under the title of

THE ACTION OF THE TURKISH BATH IN DISEASE.

The Turkish bath is simply a convenient manner of applying heat to the body, and is readily adapted to any diseased condition. It is not exhausting, as many suppose, nor is its salutary influence measured by its power to produce abundant sweating. One of the most remarkable properties of the bath is its ability to allay the sense of fatigue. There is an invigoration arising from the contact of the vitalized skin with the dry heat of the bath, which gives an increased power of drinking in oxygen, through channels previously closed, and withal there is little sensible loss of matter, what is parted with being only that for which the system has no further need.

One of the uses of ordinary perspiration, is to maintain the equilibrium of temperature, on which the safety of the individual depends. As the natural average temperature of the human body is 98° Fahrenheit, Nature has provided that this standard shall be maintained in every latitude, and under all atmospheric variations. When unusual heat is applied to the surface of the body, the system is called upon to protect itself by maintaining its equilibrium at 98°, and this is accomplished by throwing out water to be evaporated from the surface. As when water becomes vapor, a large amount of heat becomes latent, so the higher the temperature, the more abundant the flow of sweat, and the more rapid the evaporation, and the heat is carried off latent in the vapor. Thus man is enabled to endure habitual exposure to an artificial temperature of dry air as high as 400° Fah. Carpenter says: "Many instances are on record of heat from 250° to 280° being endured in dry air for a considerable length of time, even by persons unused to a particularly high temperature; and persons whose occupations are such as to require it, can sustain a much higher degree of heat, though perhaps not for any very long periods. The workmen of the late Sir F. Chantrey have been accustomed to enter a furnace in which his molds were dried, while the floor was red-hot, and a thermometer in the air stood at 360°."

Men engaged in various branches of manufacturing industry, such as ore smelting, iron foundries, rolling mills and glass works, are habitually exposed, for lengthened periods, to heat ranging from 200° to 350°, which they are able to sustain for years without any loss of vigor, or detriment to health. And this simply on account of the seven million little glands spread over the inner surface of the skin, which, by evaporation, send off the heat that would otherwise raise the temperature of the body. We know that no amount of heat can raise the temperature of water above 212°, so long as the steam is allowed to pass off. Just so a man can endure a temperature of even 600° for a time, with impunity, provided the skin acts freely and the atmosphere about him is dry, and drinks up rapidly the moisture that exhales. So far, indeed, from high temperature proving injurious, it is the adaptability of the skin to resist high artificial heat upon which the Turkish bath relies for its marvelous sanitary and curative powers.

Thus we see that there is no foundation for the popular prejudice about the hot air bath increasing the temperature to a dangerous degree. Such a prejudice is not only condemned by physiology and experience, but it is in direct antagonism to the very laws of our being. Now how comes it that, by a slight increase of heat, there should be a sudden power given to the skin to throw out moisture? and whence comes this moisture? From the blood. And to be able to furnish moisture, the blood must be brought to the skin; and this is the grand secret of the *modus operandi* of the Turkish bath. It is by equalizing the circulation, and thus removing congestion, whether of the lungs, the liver, the brain, or any internal organ, or tissue near the surface, or the skin itself. When heat is applied to the surface of the body, the blood that is feebly circulating within the trunk is brought to the surface and the extremities, and its water, loaded with effete and waste material from the system, is given up to protect the skin. If the heat is continued, all the energies of the system are aroused to bring into circulation the blood that has been stagnant and congesting the lungs or liver, or some other organ. Then all the absorbents are set to work, to take up any dropsical effusion, whether in the cellular tissue, or in the closed cavities, as the abdomen or chest, that it may be restored to the circulation and evaporated from the surface.

Then, again, by drinking pure water, the blood is replenished with wholesome material, while perspiration eliminates the water and poisonous matter from the system. Indeed, this is the most important purpose which perspiration serves. Man perspires, because perspiration, being the watery portion of the blood, carries out with it all extraneous and poisonous matter, thus remov-

ing all constitutional taint whether of scrofula, cancer, tuberculosis, or any blood disease.

The blood has to dispose of the worn out material which results from every motion of the body, or the mind. In equalizing the circulation we provide for the nutrition of the body; and the blood, while bringing fresh fibre, has in turn to remove old poison. In fact the blood, with its watery portion, is washing the whole internal man every instant of time, otherwise he returns upon himself his own pollution.

While, then, we are constantly creating the phenomena of life, we are at the same time generating the elements of death. Your own breath will kill; all that should come from you, if pent up within you, kills; it is poison, and here the Turkish bath comes to the aid of Nature, and purifies the blood more directly and thoroughly than any other means that science or ingenuity has ever before suggested. The proselytes of Mohamet believed that by the agency of the bath, barrenness was removed. With the ancient Mexicans it was used, not only by the sick, but by persons who had been stung by some poisonous reptile.

The skin, in this climate, and with our artificial life, is so much covered as to render it in a large degree inactive, and therefore a fruitful source of disease. Frequently it is in a state of partial paralysis, as is shown when entering the hot room of the bath; the face and hands feel the impression acutely and the rest of the body comparatively little. The least sensitive part of the body is that which is covered by clothing. Exposure to the light and air gives the skin more vitality, and therefore it is more active and sensitive. It is to be noted that among the intertropical peoples, where the skin was naturally kept in an active condition, the bath was used only in case of disease.

It is well known that but a comparatively small portion of the skin can become disorganized without causing death. In fact, we live through the skin. Every portion is pierced with fountains which flow with foul water so long as there are any impurities within, and with distilled water when they are expelled. Hence, the disagreeable odors that come to us as a warning. The impurities as well as the cleansing powers of man come from within. Disease and dirt are almost synonymous terms.

Thus do we have a large control over disease by means of the skin, and we can command the skin by means of heat. The skin becomes the prophylaxis of the other organs, and if there is any vitality left in the other organs, there is hope of life. The skin literally brings us in touch with the external world, and is the means of casting out the disintegrated tissues of the body, as well as the poisons produced by the operations through which life is generated during ev-

ery second of time. Therefore this is necessarily the first thing to be attended to, for if that organ is not kept in good working order, the whole body must suffer, while with it in proper condition health reigns supreme.

The practice of the bath refines the olfactory nerves, and renders them capable of noticing smells otherwise imperceptible. The healthy body is endowed with a sweet odor, described by those whose organs are sensitive enough to detect it, as resembling fresh sawed fir boards. There are odors to certain conditions of disease that are patent even to the superficial observer. Pathology, when carried to a greater perfection, will probably enable us to detect, by the nose, the existence and condition of many maladies. Herein lies a comparatively uncultivated field of diagnosis.

For the many troubles incident to childhood, the Turkish bath is a panacea. With me it has superseded all other treatment, and for carrying children through all eruptive fevers of that period, it has proved equal to every emergency. The bath has been administered to children from the time they were one month old, and on occasion daily for several months, and the result has been in every way satisfactory, notably in a case of croup. A small boy about $3\frac{1}{2}$ years old, was taken late at night with the harsh ringing cough of croup, and together with the labored breathing was in a very pitiable condition. He was taken to the hot room of the bath. At first the heat did not seem to give relief, on the contrary the symptoms apparently were aggravated. Rubbing of the arms and legs was then begun, and this was pleasant to the child. An expression of enjoyment, which was his first spoken word, encouraged perseverance. Very soon perspiration began, and then the unpleasant symptoms gradually lessened. He was kept in the hot room about an hour, until his breathing was perfectly natural and the perspiration most abundant, when he was washed off and put back to bed. He went directly to sleep; no more coughing; nor was he heard from again till after daylight the next morning. That was the last of the croup.

In the long list of diseases none seem more susceptible of relief by the hot air treatment than gout, rheumatism, and neuralgia. Gout is perhaps the least amenable, but a temperature of from 160° to 170° acts as a complete anæsthetic to the local pains of the paroxysm, and it removes also the primary cause of the gout by favoring the re-absorption of deposited urates, and their combination with oxygen, by which they cease to be injurious to the frame. Oxalic acid, a prominent product of this oxygenation, has been found in the sweat of gouty persons.

The action of the Turkish bath in rheumatism has been phenomenal, and commands the respect

and admiration of all who have investigated the subject. As this disease is indicative of an inert skin, and as the bath immediately awakens all the activities of that organ, the special poison of rheumatism is quickly eliminated and inflammation is consequently allayed. A frequent and persistent use of the bath has many times relieved what were considered intractable cases, and that which was formerly a matter of endurance for months has been reduced to weeks. The immediate relief from pain while in the hot rooms renders the treatment more than agreeable, and makes the patient desirous for its repetition, and thus the sufferer is gradually restored to his normal condition, while the freedom from continual dosing or blistering is often an object of profound gratitude. There is never any unpleasant sequela attending the Turkish bath treatment, and even when there is a tendency in the system toward the development of rheumatism, the frequent use of the bath will counteract and relieve it.

The recuperating force of the Turkish bath in neuralgia is shown by the following case. "Billy Edwards," a noted light weight, was brought to the Institution by his physician in January, 1875. He had suffered the excruciating torments of facial neuralgia, or true tic, over two months, and found no relief, though he had applied to several prominent physicians in New York City. He was given two and sometimes three baths a day, remaining under treatment ten days, when he left, entirely relieved of pain, and feeling quite well.

In the treatment of tuberculosis, the Turkish bath has proved a reliable and efficient agent. It has been shown by a series of experiments that the earlier stages of the malady are susceptible of much amelioration by the use of the hot air treatment, which comes from its power of altering the chemical and electrical conditions of the organic structures of the body, and abstracting its fluids. The importance of the functions of the skin in the pathology and treatment of phthisis is conceded by all. By eliminating poisons through its pores we restore its respiratory action, and so enable it to assist the lungs in their important functions. In the latter stages of this malady profuse sweating is one of the worst symptoms which we have to combat, but the direct action of the bath has been more strongly shown in removing night sweats than in any other symptom. At such times it is important to enlist every organ that can assist in the work. Hot air promotes the chemical changes that are constantly going on in the lungs, and stimulates the skin to its respiratory functions. The more perfectly this work is performed the greater the success in the treatment. As yet no agent has been found to do this work equally well.

Dr. Leared, one of the physicians of the London Consumptive Hospital, wrote as follows.

"Three patients affected with consumption have been for some time subjected to the Turkish bath treatment. They were all in an advanced stage of the disease, as the tuberculous deposit in the lungs was not only considerable, but had become softened or ulcerated. The general symptoms of all were greatly improved, but the most remarkable circumstance is, that in one case, the signs indicating softened tubercles have disappeared, the lung becoming comparatively dry and solid."

These patients were admitted to the hot chamber for an hour every second day, the temperature not exceeding 140°.

Sir John Fife, Senior Surgeon to the Newcastle Infirmary, says: "Great must be the value of a process which in a few minutes will secure a general diaphoresis, bring the circulation to the extremities, and equalize arterial action. It may be safe to conclude that it will be of service in every case of internal congestion, and its effects are most remarkable in obviating disorders and palliating the diseases of the liver and kidneys; for it not only distributes a more equal circulation, but allays spasm in the excretory ducts, and I am unable to point out any class of cutaneous diseases in which the Turkish bath may not prove an effectual treatment or an important auxiliary. In bronchial inflammation or laryngeal, the surface affected is instantaneously reached.

Prof. H. von Ziemssen, in his new Medical Encyclopædia, in the part devoted to kidney diseases, says: "Diaphoresis constitutes the most reliable means of reducing the dangerous dropsy. It is also the only treatment from which I feel justified in expecting a curative action on the process of disease going on in the kidneys. In this sense an efficient diaphoretic treatment fulfils not only the *indicatio symptomatrica*, but actually also the *indicatio morbis*, in a better and surer manner than any other mode of treatment. In chronic parenchymatous nephritis, I have repeatedly found that as soon as I succeeded in producing a profuse sweat every day, a more abundant flow of urine set in, and the percentage of albumen became less. We must remember that in the chronic form of Bright's disease we have to deal with a much more extensive alteration, both of the vessels and tissues, and if we expect to effect a cure by diaphoresis we must set to work in a thoroughly methodical manner and carry out the treatment with obstinate pertinacity. The method most agreeable to the patient, and most effectual, is to heat the skin in dry hot air, as is done in the so-called Turkish bath."

Dr. Sheppard, in charge of Colney Hatch Insane Asylum, Eng., says, "There is an unmistakeable dread of the hot air bath as regards those who suffer from heart disease or a tendency thereto, arising from a fear of undue stimulation of the circulatory system, but it is remarkable

that the very contrary effect is produced. The bath tranquilizes and subdues."

On this point Sir John Fife adds, "In cases of heart disease the patients have undergone the process with unlooked for benefit; the extreme heat exerts less influence on the heart than the ordinary bath."

Dr. Erasmus Wilson says, "Scrofula is imperfect nutrition, cancer is imperfect nutrition, indigestion, rheumatism, gout, neuralgia, are imperfect nutrition. Give a power by which nutrition can be regulated, and you immediately control these various diseases. Now there is no power by which the proper direction of nutrition can be attained, excepting through the skin, and that I believe to be the explanation of the extraordinary results which seem to flow from the bath. The bath does no more than regulate nutrition."

In our own country, such physicians as Dr. W. A. Hammond, Dr. Austin Flint, Senior, Dr. Lewis A. Sayre, Dr. John T. Metcalf, Dr. W. H. Van Buren, Dr. George T. Elliott, Jr., Dr. F. N. Otis, and many others, have borne strong testimony to the great value of the Turkish bath in disease.

In this flood of evidence, which is not a tithe of what might be adduced, it is apparent that the Turkish bath has the effect of different medicines, in that it removes the symptoms for which they are administered; thus it is a cathartic, a diuretic, a tonic, a detersive, a narcotic, but the effect is produced only when there is cause. It will bring sleep to the patient suffering from insomnia, but will not, like opium, make the healthy man drowsy; and relieve constipation without bringing on diarrhoea to the healthy, as aloes would. It is thus a drug which administers itself according to the needs, and brings no evil consequences, working only to place the system in a natural and healthy condition.

With a full knowledge of the uses of different degrees of temperature, we have an entire command over those acute disorders which constitute nine-tenths of our maladies.

The practicing physician, with caloric as his servant, can frequently ward off and disperse an attack of disease.

To him who would be more than a mere physician, who would seek to prevent disease as well as to cure it, this subject opens a field of immense opportunity, both as regards himself, and the community in which he lives.

The signs of the times are more than ever encouraging for the future. The medical horizon is continually broadening. The constant discovery of new remedies shows dissatisfaction with the past. The more liberal of our profession are welcoming all helpers. Already preventive medicine is stepping forward in the march of progress, and among the agencies to aid in the material

welfare of our race, both in prevention and cure, the Turkish bath will take rank second to none.

We are beginning to understand the value of the sun's rays, which the Egyptians, centuries ago, symbolized by the human hand. The sun is the source of all our physical blessings, and heat its most important effect.

Certainly a beginning in the use of the Turkish bath as a remedial agent, has been made. It has passed the experimental stage, and in the not distant future, medical science will necessarily be compelled to adjust itself in harmony with the facts so readily at hand, and so easy of demonstration.

What has been uttered is prompted simply by a strong feeling that from a study of this subject mankind may derive an immense benefit, and that our profession should take the lead in the grand work.

The Turkish bath has now been before the American public for several years, and by no means has it been accepted as fully as its merits warrant, but as Lamartine said, "Time respects only that in which he has himself a part."

Dr. Thudichum, in an able monograph read before the Medical Society of London, concluded in these words, "I have now put before you what I think right, and what we should develop. A boon to mankind, your nation, and every individual in this room. Hot air, combined with cold effusions, with shampooing, with exposure of the body to light and air, await your approval as medical agents, and your application to those under your care. I hope that you will seize the opportunity, and secure for this society a share in the merit, similar to that of which Hippocrates was proud, of having introduced the bath in the treatment of disease."

NOTES ON THE TREATMENT OF SYPHILIS. ITS EVOLUTION AND PRESENT STATUS.

Read before the Ohio State Medical Society, June 17, 1891.

BY WILLIAM THOMAS CORLETT, M.D., L.R.C.P.,
LONDON.

OF CLEVELAND, O.

Professor of Dermatology in Western Reserve University, Medical Department, Consulting Physician for Diseases of the Skin, to Charity Hospital, St. Alexis Hospital, and the Hospital for Women and Children.

The treatment of syphilis has completed a cycle, and to-day we stand upon the same ground that our medical fathers occupied nearly four hundred years ago. Familiar as they were with gonorrhoea, which even in the days of Moses was known as a "running issue out of the flesh;" familiar with the local contagious ulcers of the genitals, which had been accurately described by the most ancient medical writers of Arabia, Alexandria, Greece and Rome, they were, in 1494, amazed at the advent of a disease such as they

had never seen before and whose ravages they were unable to assuage. For nearly half a century these three diseases retained their identity in medical writings, and not until the generation passed away which had observed its invasion did confusion prevail to retard the course of future progress.

Thus the first authentic observations of the treatment of syphilis were made while it enjoyed the distinction of being a disease *sue generis*.

It soon became known that mercury had the power of controlling the disease, and it was adopted as the standard treatment. But the indiscriminate use of this potent drug led to results even worse than those of the disease itself. It was only four years after its first appearance in Europe that Gaspar Torella, physician to Pope Alexander VI, directed that the ointment then in use be reduced in strength, and soon after John de Vego, a Genoese, obtained brilliant results with a plaster which was a compound of mercury with aromatics.

Finally the belief obtained that these diseases, having a common origin in sexual contact, were alike in nature, which led to the abandonment of mercury as a specific. This was in the age of depletion, and blood-letting, starving, purging and sweating followed as a natural sequence. Nor were drugs abandoned; the new world offered numerous plants that were held in high repute among the Indians of the American Continent. Foremost of these stood guaiacum, which as early as 1508 was imported into Spain, where it soon attracted attention from the wonderful cures attributed to it. Ten years later its fame extended into Italy and Germany; special treatises were devoted to it, and guaiacum remained the recognized treatment for the "venereal disease" during the sixteenth century.

Then came sarsaparilla, which in turn threatened to supersede guaiacum and which to this day holds a high position in the popular mind as a "blood purifier" *par excellence*. But many cases, those we now know to be syphilitic, did not yield to this form of treatment, and mercury was added to the "decoction of the woods." It was in this way the decoction of Zittman became famous, which even now is extolled by some who think it a useful adjuvant in the treatment of constitutional syphilis.

During the seventeenth and eighteenth centuries there was no consensus of medical thought, consequently there was no stable or definite form of treatment. Some with retrospective bent adopted the "dry treatment of the Arabians," which aside from certain annoying observances, consisted in taking a mercurial pill morning and evening.¹

In 1758 a report was made to the Royal Academy of Sciences of Stockholm entitled "The Lo-

belia, a Certain Remedy Against the Venereal Disease. Discovered by Peter Kalin."² In this quaint document the writer describes *in extenso* its employment by the Indians of North America, the facility with which the venereal disease was cured by it, how the secret was obtained from them, and finally a comparison in which is shown its advantages over the treatment by mercury.

With the beginning of the nineteenth century an important advancement had taken place. Benjamin Bell had eliminated gonorrhœa from syphilis in 1793, and as if to clear the way for a more definite system of therapeutical investigation which now became possible, a new system of treatment was adopted; and it became by far more general than any other since the distinct features of the different venereal diseases have been lost sight of. At this time, too, a reaction was beginning to show itself against the heroic measures for the relief of disease in general. The new method was called the "Simple Treatment," and corresponded to our expectant treatment. As it was not known that the diseases, which at this time included all venereal sores, tended to recovery, the new treatment was hailed with enthusiasm. Nor was the enthusiasm ill-timed, for it taught that the disease was self-limited; that relapses which were attributed to certain drugs, notably mercury, were a feature of the disease itself, and that much smaller doses of mercury were capable of controlling syphilis than had previously been given.

A second great advancement was made in 1831, when Dr. Robert Williams advocated the iodide of potassium in the treatment of syphilis. The favorable report of its use by Ricord of Paris, and the publication by Wallace, of Dublin, in 1836, directed general attention to the drug, and it soon became extensively used.

When it became known that syphilis, if left to the natural eliminative forces of the body, became extinct in time, there was an attempt to hasten the *vis medicatrix nature* by stimulating the surface with blisters and the application of tartar emetic ointment. In the same direction, but by far the most important of these procedures was that of syphilization, which was conceived by Anzias in 1846, in the following way: In endeavoring to inoculate some of the lower animals with syphilis he obtained, as he supposed, a saturation or tolerance of the poison whereby the syphilized enjoyed immunity from further inoculation as well as from the ill effects that were known to follow the first. But experiments made so extensively by Boeck, of Sweden, and others, have relegated syphilization to the long list of abandoned methods which adorn the pages of medical history.

It was not, however, until Ricord began a

¹ Bumstead, Venereal Diseases, New York, 1866.

² Dr. Heller's Medical Notes, 1758.

systematic study of venereal sores at the Hôpital du Midi, in 1850, which enabled Bassereau two years later to announce to the world the doctrine of duality, that the modern epoch in the treatment of syphilis really began. From this time it has been separated from extraneous maladies which are unlike in nature and which differ essentially as to treatment. Note the result: Uniformity of method has succeeded the indefinite age of "new systems" and "new schools;" a uniformity, too, without the loss of individual effort to attain the highest end.

Thus systematized, the primary object in the treatment of syphilis, is to prevent systemic infection. With this in view the initial lesion has been cauterized after the manner of Ricord; it has been excised as practiced by Auspitz and Kolliker, but these procedures have failed to prevent the subsequent phenomena of syphilis. More recently Otis has advised the destruction, and where practical the excision of the initial lesion, not so much to prevent systemic infection as to destroy a focus of infection and as the quickest way of healing the sore.³

In most cases the application of mercury will cause the lesion to disappear, and except when accompanied by suppuration or necrosis, is the best means at our command. With suppuration iodoform is very extensively used; aristol is a new preparation free from the disagreeable odor of iodoform, and said to be even more efficacious; while antifebrine, in the writer's experience of three months, promises to supersede all other applications in this particular condition. But it is not with the primary sore that error is most liable to occur, for it usually disappears of its own accord; it is the systemic management, the persistent warfare against the syphilitic virus and its sequelæ that appear to be insufficiently understood by many who essay to treat the disease.

First, it is well to bear in mind that the virus may in time be eliminated by the natural forces of the body.

Second, the drug, and the only one, that is positively known to possess any curative influence over syphilis, is mercury. Under various disguises it has been given for centuries, and to-day its virtues are attributed to waters, and to nostrums innumerable. But a careful analysis enables us to affirm, that under its use the various manifestations of the disease disappear, relapses are less frequent, and finally the organism becomes free from the baneful influence and may be infected again. When to begin mercurial treatment is a point on which opinions differ. Hutchinson⁴ claims for mercury the power of aborting the syphilitic processes; he therefore gives it with the first appearance of the primary

sore. Lassar, in a personal interview, advocated its early use, "because if the disease does not prove to be syphilis it does no harm; whereas if it be specific the sooner mercury is given the better for the patient." Others again withhold the drug until secondary or systemic symptoms appear.

Doubtless the best course is to begin the use of mercury as soon as the diagnosis of syphilis is made. Previous to this the time may be profitably occupied by placing the patient under proper hygienic influences, and in the use of tonics such as iron, vegetable bitters and mineral acids, which will prove useful adjuvants to the subsequent course of mercury.

The special form of mercury that is advisable to use will depend largely on the individual requirements of a given case. Generally speaking, the protosalts are to be preferred to the bisalts at the beginning, as calomel, mercury with chalk, or the blue pill either alone or combined with iron, as in formula suggested by Bumstead many years ago.⁵ In infantile syphilis, mercury with chalk is largely given in England, and has given the writer the best results. It was formerly thought to obtain a therapeutic effect of mercury it was necessary to produce salivation; we now know that the best results are gained by the continued use of the drug in quantities barely sufficient to produce tenderness of the gums.

To guard against the disagreeable complications which may occur in the mouth, the following simple rules should be observed: Before beginning the mercurial treatment, the teeth must receive attention at the hands of a dentist, and all decayed teeth either filled or removed. After eating they should be brushed with a soft brush to remove all particles of food, and if tenderness supervene a saturated solution of chlorate of potassium may be used as a mouth wash.

From the most remote times various methods have been employed to introduce mercury into the organism; plasters, inunctions, baths and its ingestion by the mouth, have all had their ardent advocates.

Fumigation, which was revived by Langston Parker of Birmingham, is an efficient way of giving it and free from some of the disagreeable features of other external methods. Of late, hypodermic or intermuscular injections have been extensively used, as advised by Scarenzio, of Milan, in 1864. Lewin has especially identified himself with this form of treatment, and it has been used almost exclusively in the extensive wards of the Charité Hospital at Berlin, for the last thirty years, which of itself is a sufficient guarantee of its value and the high estimate placed upon it by this most eminent syphilographer.

³ Clinical Lectures on Syphilis, by Fessenden N. Otis, N. Y., 1881.

⁴ London Lancet.

⁵ Venereal Diseases, New York, 1866.

But he is best able to treat syphilis who recognizes the special value of the several methods at his command. For reasons that are apparent to all, ingestion by the mouth is the one most in vogue, and when well borne there is none better. Frequently, however, gastric disturbances necessitate its discontinuance, when recourse must be had to one of the other ways of administration. The choice must be determined by the physical as well as the social statute of the patient.

Inunction is very largely used both in this country and in Europe, and forms the essential treatment at the numerous springs that have been vaunted for the cure of syphilis. The skin should be prepared for the absorption of mercury by taking a warm bath with soap, best at night. Then from half to a drachm of the strong ointment should be rubbed into the skin before the fire, either by the patient or an attendant with rubber gloves.

To those who can not subject themselves to this uncleanly process, fumigation may with equal efficacy be adopted. In fact the latter offers the best means of treatment when superficial lesions are present, as in the early syphilides. But many patients cannot carry out even this, and a method less liable to exposure must be used. Here is a field for hypodermic injections, which have but one objection so far as the writer's experience goes, and that is the pain, which continues three or four hours thereafter. Again when it is necessary to obtain a rapid effect of mercury, hypodermic injections afford a most efficient means. The formula that has given the writer the best results is the one used at the Poliklinik for skin and venereal diseases at Berlin:

R. Hydrarg. bichlor., gr. $\frac{1}{4}$.
Sod. chlor., gr. $\frac{3}{4}$.
Aquae dest., \mathfrak{z} i. \mathfrak{m} .
Sig.— \mathfrak{z} i two or three times weekly.

I have never seen abscess or other inflammation follow this injection.

A fertile source of error lies in supplanting mercury by the iodine compounds. If one will take sufficient pains to investigate the treatment as carried on at the iodine springs at Halle, in Austria, one cannot but be impressed at the frequency with which the patients return after having been discharged free from all manifestations of the disease. This leads us to consider the rôle iodine plays in the management of syphilis.

After a certain though variable time the lesions, which have been superficial and evanescent, assume a more destructive and indolent form; new formations appear on the surface, others occur in the various structures within. This is known as the tertiary or stage of sequelæ. The tumors and destructive processes of this stage often endanger important organs or even life itself; these call for immediate relief. In iodine and its salts we have

the best known agent for causing the rapid absorption of tissue enlargements which, as is well known, constitute the essential processes in lesions of tertiary syphilis. And clinical experience has demonstrated that these collections of granular tissue, whether in the stage of formation or decay, disappear and heal under its use. Nowhere is its action more marked than in lesions of the brain, and nowhere is it followed by more satisfactory results. In destructive processes of the upper air passages, too, its effect is almost marvelous.

The dose of the iodide of potassium, the preparation generally employed, varies greatly in different persons. I recall to mind a woman treated at the Blackfriars' Hospital for Skin Diseases, in London, who obtained the full benefit of the drug with a quarter of a grain, in fact a larger quantity produced iodism. Again, fifteen, thirty, sixty and even two hundred grains per diem is required to influence the disease. When large doses are required a combination of the iodide of ammonium and sodium, as recommended by Berkley Hill, is to be preferred.

The salts of iodine are best given dissolved in milk taken immediately before meals. When taken after eating water is the best vehicle, and it should be taken an hour after the meal. Generally better results follow the so-called mixed treatment, and as iodine should only be given late in the course of the disease, the persalts of mercury are selected, as in the following:

R. Hydrarg. perchlor., gr. iij.
Kal. iod., \mathfrak{z} j.
Aquam add., \mathfrak{z} ij. \mathfrak{m} .
Sig.—Ten drops in water after meals.

As soon as the special indications for iodine have disappeared it should be discontinued, and recourse had to mercury. It has been the writer's experience in difficult cases to find that the salts of potassium have almost invariably been given early in the disease. This leads to the conclusion, which is also entertained by others, that the salts of iodine not only are ineffective early in syphilis, but are positively harmful.

It is also important to know how long mercury should be continued. This will vary in different cases, for in some the disease may disappear in three months, while as many years is the allotted time, even under the most systematic treatment. As a rule, it should be continued at least six months after the last indication of systemic contamination has disappeared. After the continuous use of mercury has been withheld it is advisable to return to it at given periods for one or two years. It is my custom, when practical, to give two courses of six weeks each the first year, and one course the second year.

But there are cases of syphilis that are conspicuous exceptions so far as treatment is concerned. First, there are those associated with debilitating

conditions, such as tuberculosis, cancer and old age. Here the treatment must necessarily be varied, and oftentimes mercury plays an inconspicuous rôle. There are other cases, fortunately rare, over which mercury has no specific influence. On this account grave doubts may arise as to the correctness of the diagnosis. Three cases of this kind under observation were in young, robust subjects, which yielded finally to $\frac{1}{2}$ th grain doses of the chloride of gold and sodium, taken from four to six times a day.

As accessories to medical treatment the patient should abstain from the use of tobacco, and be advised as to a regular course of living best suited to promote his physical welfare. Special attention should be given to the organs of elimination, and to facilitate their action water should be partaken of freely. A hot bath with soap should be taken every night, or a Turkish bath once or twice a week.

In this connection, and to emphasize the foregoing, a word about the treatment as carried on at the various springs that have taken such a hold on the popular mind, and which have become so much in vogue withal. The most celebrated establishment in Europe is doubtless that at Aix-la-Chapelle. It is claimed that the sulphur water at Aix stimulates the emunctories so that a larger quantity of mercury may be given and eliminated without causing ill effects. The principal advantage that these and other springs have over the treatment at home arises not so much from the water as from the care with which every detail of treatment is carried out. First, the diet is regulated so that a sufficient amount of nourishment is taken, and articles liable to cause disturbances of digestion, such as fruits and indigestible dishes, are withheld. The patient begins the day with a light breakfast, afterwards he walks if the weather be fine, and then takes a hot bath; after which a drachm of the strong mercurial ointment is rubbed into the skin by an attendant. He remains in a warm room about two hours and drinks during this time from one to two pints of sulphur water. He then walks, dines, and walks again, partakes of a light supper and goes early to bed. After this routine has been repeated daily for about six weeks, the lesions of syphilis have usually disappeared, and he is sent home, to return at the end of two months. The patient's attention is diverted from his malady by amusements of various kinds, so the syphilitic usually finds his stay at Aix-la-Chapelle both pleasant and profitable.

In this country the Hot Springs of Arkansas are frequented by those who think to get the disease "boiled out" of them. But it is quite generally recognized by syphilographers that the water has no specific effect on syphilis.

PRIMARY PERIOSTITIS OF THE MASTOID.

Read before the Section of Otology and Laryngology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY H. V. WÜRDEMAN, M.D.,
OF MILWAUKEE, WIS.

My object in reporting these cases, beyond the fact that primary periostitis is rare, is to show the advisability of prompt action and radical treatment in all post-aural inflammations.

Case 1.—May 30, 1890. Mrs. M., æt. 30, a seamstress. Was convalescing from an attack of facial erysipelas, the last manifestations of which had apparently left four weeks previously. I was called in consultation by Dr. U. O. B. Wingate, on account of a painful swelling behind the left ear, which had been first observed about a week before. She had had fever for several days, and upon my examination the temperature was found to be 101° . The mastoidal region was quite boggy and exquisitely tender. The hearing distance was normal; an examination by the speculum and mirror did not even reveal congestion of the membrane. Likewise the Eustachian tubes and pharynx were apparently normal. On the same day I made a Wilde's incision, without anæsthesia, through the swollen area down to the bone. Neither pus nor necrosis were found, but the periosteum was apparently thickened. The wound was antiseptically dressed and allowed to heal from the bottom, its lips being stretched apart by strips of iodoform gauze. The operation relieved all the disagreeable symptoms immediately, the wound being healed in one week.

Case 2.—August 1, 1890. Mr. W., æt. 54, manager of large corporation. Had acute sup-puration in the left ear following epidemic influenza, but no discharge had been observed for four months. Had been under the care of an aurist for a portion of that time. He consulted me about a red and tender swelling of the left mastoid, which had commenced two days before. Temperature by mouth, 100° . Examination of the left ear showed H. D. = voice 3 M. Could not hear whisper or watch. A large perforation of the membrana vibrans existed, but no pus was visible. Leeches were applied to the mastoid, and in three days the post-aural symptoms seemed to be entirely relieved. The edge of the drum head was pared with a probe-pointed knife, and touched with 10 per cent. argent nit. on several occasions, until on the 14th of the month the perforation had nearly closed. H. D. = watch at 3 cm.

On the next day he returned to me with fever, the mastoid being again red and tender. There was no discharge to be observed in the middle ear. Leeches were again applied, the mastoid painted with tinct. iod. and antiphlogistic treatment used

the ensuing five days. The patient was confined to his room, but on account of his dread of an operation none was even suggested until such became imperative. After a very painful night fluctuation was evident, and I made a Wilde's incision, without anæsthesia, liberating several drachms of pus, which spurted from the wound with considerable force. The periosteum was much thickened and detached from the bone. In the line of incision a soft spot, about the size of a dime, was seen. This was scraped out with a sharp spoon and a drainage tube inserted. The wound was packed with iodoform gauze and bandaged. The incision was made for diagnostic purposes, but I fully expected to have to trephine the mastoid.

To my surprise on again visiting the patient I found all the symptoms relieved by the operation, he having passed a comfortable night. On dressing the wound but little pus was found and the graver operation was postponed, particularly as no sinuses could be seen in the bone. On the next dressing the wound was dry, and from this time it was allowed to close. Ten days later it had healed over. By subsequent treatment the membrana tympani was restored, and on Oct. 1, H. D. by watch = 100 cm. The patient has been apparently well since that time.

The operation was made on the first case in the stage of beginning inflammation before the formation of pus, but by the local abstraction of blood a further stage was aborted. In the second instance, the local inflammation was due to an extension of the original affection from the periosteum of the middle ear to that of the mastoid bone, and was not recognized until after pus had formed. In this case it is evident that only the covering of the mastoid and not its lining was involved. The process remained quiescent at some point in the periosteum for four months, then lighting up an active inflammation, the product of which was pus. In the first case the periostitis was undoubtedly primary, as the middle ear and canal had never been involved in an inflammatory process. In the second instance, upon first sight it seemed that the periosteum of the mastoid was the only part of the membrane involved, yet on account of the preëxisting middle ear disease we must class it as a sequel of the original affection. A remarkable event in the history of the second case was the renewal of the drum head, a process which seldom occurs in a person of such age.

Most cases showing these symptoms involve deeper structures than the periosteum and necessitate the graver operation of chiseling or trephining the mastoid. When a painful swelling appears in this region I am in favor of immediate incision, not only for the purpose of relieving the inflammatory symptoms by local blood-letting, or of releasing pus, but also as a means of diag-

nosis, as the incision may easily be extended for the operation of trephining. Wilde's incision in itself is void of danger, easy of accomplishment, and may be relied upon for relieving local inflammation by a thorough depletion of the blood vessels.

805 Grand Avenue.

FRIEDRICH'S ATAXIA; ITS RELATION TO THE CONDUCTING PATHS IN THE SPINAL CORD.

BY DAVID INGLIS, M.D.,
OF DETROIT, MICH.

At the Congress of American Physicians and Surgeons, Dr. David Inglis, of Detroit, read a paper upon the above subject before the American Neurological Association.

He reports in brief, a case of Friedrich's ataxia in a boy of six years of age, in which the symptoms conformed accurately to Friedrich's own summary of the characters of the disease, viz.: "Impairment in the combination and harmony of movements developing gradually and spreading from the lower to the upper half of the body, and always involving finally the organs of speech; sensibility and the functions of the special senses and of the brain being intact; paralysis of the sphincters and trophic disturbances are absent; less common phenomena are curvature of the spine, sensations of vertigo and nystagmus. From a clinical point of view we must regard the disease as a progressive paralysis of the faculty of combination of movements."

A review of the thirteen recorded autopsies shows a practical agreement that the pathological condition underlying the disease consists in a progressive sclerosis which always affects the column of Gall, the column of Burdach also, but not so completely, the direct cerebellar tracts with Clarke's column in most cases and the crossed pyramidal tract in some cases, but the sclerosis is here not so intense. We have to deal with a disease of the tracts which degenerate upward, which are usually looked upon as centrifugal and as conveying sensory impulses.

Author contends that the symptoms of Friedrich's ataxia afford a demonstration that these tracts do not convey sensory impulses upward, for sensation is not impaired, but that they are the main tracts for the conveyance of coördinated motor impulses downwards; that their anatomical relations with the medulla, cerebellum and mid-brain, as well as the facts of Friedrich's disease agree in showing them to act to coördinate motor impulses of the mid-brain, cerebellum and higher and lower levels of the cord.

The facts of Embryology strengthen this theory; at the end of the foetal life, at a time when the pyramidal tracts are undeveloped, the posterior

columns and direct cerebular tracts are complete. Their function evidently begins at once after birth. When we remember that the new-born infant is characterized, not by voluntary control of its muscles, not by accuracy of sense perception, but by an extensive coördination of involuntary motor functions, the conclusion is easy, that these, the only tracts fully developed at birth, subserve these purposes.

The direction of Wallerian degeneration is not necessarily the same as the direction of normal physiological impulses in any given nerve tract.

IMPROVED EAR ELECTRODES.

BY SETH S. BISHOP, M.D.,
OF CHICAGO.

These electrodes consist of two metallic cones covered with chamois, and held in position for treatment by an elastic ribbon buckled around the head.

The tips of the cones are moistened before inserting them in the external auditory canal. In order to keep them clean, it is well to place a small covering of cotton, moistened with warm water, over the tips of the cones while in use.

It is a simple matter to adjust the cones to heads of any size by having one or two extra apertures in the ribbon, through which one of the cones can be easily passed. Or a second buckle can be put between the cones, at the back of the head, in order to alter the distance.

The ribbon should never be buckled so firmly as to occasion uncomfortable pressure.

The advantages of these electrodes over the old ones commonly employed for ear treatment, are the following:

1. The electric current can be concentrated as much as is possible in the ears, instead of being diffused over the side of the head and face.
2. There is no necessity for filling the auditory canal with water, and thus macerating and relaxing the drum head.
3. The patient is relieved of the irksomeness of holding the electrodes in position, a freedom fully appreciated by those who have had experi-

ence in the old way. With the cones in position, the patient can take a comfortable treatment while looking over the morning paper or illustrated magazine. This converts a treatment that was formerly a bore into a comparative luxury.

Chas. Truax, Greene and Co., made these for me.

BOOK REVIEWS.

DISEASES OF THE NASAL ORGANS AND NASO-PHARYNX.
By WHITFIELD WARD, A.M. M.D.

This little work from the house of Putnam's Sons, is intended for the student and general practitioner, rather than for the specialist, and admirably fulfills its mission. A short practical treatise upon rhinology is in demand. Dr. Ward has certainly met the requirements of the general practitioners in an admirable manner.

TRANSACTIONS OF THE SOUTH CAROLINA MEDICAL ASSOCIATION. It certainly cannot be denied that there is a medical "New South." The professional ranks of the South contain many of our ablest men. In the case of those Southerners who practice in the large cities, excellent contributions to medical progress should be expected. Many of the best contributions to current medical literature are from the pens of southern doctors who do laborious country practice. The best representative society in America to-day is undoubtedly the Southern Surgical Association, members of which have contributed to the proceedings of the South Carolina Society. The present volume of transactions contains several classical and interesting articles. The papers by Dr. Kollock on abdominal section, R. A. Kinloch on drainage of wounds, and of Dr. M. P. Ravenal on general anæsthesia are especially worthy of commendation.

ESSENTIALS OF ANATOMY AND MANUAL OF PRACTICAL DISSECTION. By CHAS. B. NANCREDE, M.D. Professor of Surgery in the University of Michigan.

This is the third edition of Dr. Nancrede's work, and has been improved by the addition of osteological plates. The colored plates of anatomical studies in this book are excellent, the publisher having spared no pains or expense in their preparation.

Professor Nancrede's reputation is such that it is hardly necessary to say that the subject matter of the work is judiciously selected and arranged, and fully up to date. The book is published by W. B. Saunders.

MEMORIALS TO THE LATE DR. LEIDY.—The friends of the late Professor Joseph Leidy, of the University of Pennsylvania, are desirous of raising a memorial fund of \$100,000 to perpetuate the name of Leidy in that institution. One-half of that sum will go to the foundation of a museum, to be named after him; also an equal amount, if it can be promptly accumulated, will be devoted to the establishment of a Leidy chair of anatomy.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to
JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
NO. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues
to the Treasurer, Richard J. Dunglison, M.D., Lock Box 1274, Phila-
delphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, OCTOBER 31, 1891.

MEDICAL CRISIS IN CHINA: THE FIELD FOR
MEDICINE IN THE ORIENT.

In no half-civilized country of the Orient has medical missionary effort been expended with more liberality than in China. And yet to-day the feeling of insecurity is such that it would not be at all surprising if all that has been done should be wiped out in a day. A wave of rebellion and superstition is reported to be rolling over that vast empire, not wholly sparing the more enlightened and progressive sea-board cities. The Chinese mob, it is said, is incited against American and British missions by a belief that these foreigners use the eyes and other organs of Chinese children in the manufacture of medicines, and that these children are stolen or bought for pharmacal purposes. Denials of prejudices such as these are vain. In the mind of more than one European official resident in China, the only remedy for the present dangerous tension will be found in the throwing open to an official inspection by the Chinese government, the doors of all the hospitals, asylums and schools supported by foreign societies. This has not hitherto been the system of management, but it is recommended as an unobjectionable and feasible manner of counteracting the false reports that are spread by the leaders of the mob element.

Wherever the influence of educated medical men has been felt personally by the Chinese, the individual results—and from them spreading out in wider circles—have been markedly beneficial. Both the Chinese and the foreigners have been benefited by the good done by, and the sentiment created around the medical missions, hospitals, and schools. To quote an expression from a recent address of DR. STEPHEN SMITH of New York, "it is said that China was opened up with the point of the lancet," by the veteran DR. PETER PARKER, late of Canton. In some heathen lands the multitudes throng around the medical missions, and they have to be restrained from offering sacrifice to the missionaries, as in the days of ST. PAUL. The missionary may be respected, but the medical missionary is almost an object of worship. His cures and surgical operations are miracles to a people whose knowledge of their bodies is limited to their integument, teeth and tongue, and who believe, after centuries of opportunity to know better, that a man's brains are located in his stomach. Korea, a "hermit-nation" until a few years ago, was opened by the probe of military surgery in the hand of a missionary doctor, DR. ALLEN, who happened to be on hand shortly after a battle or *emeute*. Then too, the kindly treatment accorded to the sick in the hospitals is so diametrically opposed to the cruelties of native practice, that these hospitals become the safest spots in their cities. An English consul at Canton, during threatening times, made this memorable remark: "The hospital is safer than a gunboat." Almost without exception witchcraft, mingled with cruelty, is the medical system of barbarous peoples—and as an extreme example, and one not very well known, we may mention the treatment accorded to twin-births in Cameroons, West Africa; where under the sanction of the witch-doctors, all multiple births are destroyed before a day is over, to do away with the ill-luck they are supposed to bring, and in some tribes the mother is put to death, and in some others both of the misguided parents are put out of the way along with their progeny—so that it is no exaggeration to say that the least skilled medical missionary who ever went among the heathen has more of the godlike and worship-worthy about him than the best god the tribes he visits can possibly produce. This is seen and appreciated in an espe-

cial manner in those lands where the foreign doctors extend their care to the lunatic and forlorn leper; the treatment of insanity among uncivilized peoples has been summed up under three heads, either neglect with starvation, death by torture, or burial while yet alive. What wonder, then, if these peoples mistake the educated physician for a god! One of the names adopted among the Chinese to describe a medical mission is "The Universal Benevolent Healing Office," and many a spontaneous gift finds its way from mandarin and merchant into the coffers of the hospital.

The Rev. Dr. MOFFAT, LIVINGSTONE's father-in-law, has left on record a striking saying as to the value of a skilful medical man in foreign fields to the effect that "A medical missionary is a missionary and a half, or rather he is a double missionary." But now-a-days the converse is sometimes stated as the best method to insure success in the foreign fields, namely, medical missionaries should be sent forth not singly, but in pairs; in India especially, it has been found advantageous to have a female physician as one of the staff. The physician is almost always the first to gain a footing in any field that is entirely new. The sick heathen can appreciate a good dose of medicine even while as yet the language of his doctor is only dimly understood. And we believe it was the great LIVINGSTONE himself who many years ago, remarked that the best pioneer in a new and rude country was a well-filled medicine chest. MACKAY, of Uganda, who both administered medicine and did some surgery, often felt the need of a better acquaintance with the healing art and the companionship of a fully qualified medical comrade. So that the field of medicine is the world, the dark depths of Africa as well as the teeming fields of Asia.

CÆSAREAN SECTION TWICE PERFORMED IN THE SAME WOMEN. FOUR RECOVERIES.

One woman in France and another in Pennsylvania have, early in the current year, undergone Cæsarean section a second time. In other words, there have been four operations equally divided between two individuals; also four recoveries. To treat of the case of the foreign lady first: She was a resident of Pontoise, aged 24, the patient of a surgeon named CRIMAIL. She was not

rachitic, but had a pelvis that was uniformly contracted. Her first Cæsarean section was done in October, 1888, and the second in February last. In order to provide against the possibility of another pregnancy, the surgeon "unsexed" his patient by placing—during the second operation—a double ligature upon each Fallopian tube, a short distance from the uterus, and then divided the tubes between the ligatures. The uterus was then sutured, dressings treated with iodoform were used, and a good recovery resulted. The American case occurred in the practice of Dr. CHARLES P. NOBLE, of Philadelphia, and was reported by him to the Gynecological Society of Baltimore, in March, 1891. In this case Dr. HOWARD A. KELLY performed the first section. The uterine wound incompletely healed, and there remained a fistula from the cavity of the uterus to and through the abdominal wall. Notwithstanding this outlet, conception again took place. For several weeks the amniotic bag presented at the opening, so that during that time there was nothing between the fœtus and the outside world but the thin amniotic sac. This sac ruptured at the thirty-third week. The patient had a generally contracted pelvis, and there was besides a mass of fibrous tissue behind the cervix, which had been left by the previous Cæsarean labor. If the patient had been left to Nature, the fœtus must have been expelled per fistulam and not per vaginam. In performing the second operation, the fistula was enlarged to incision from below upwards; the peritoneal cavity was opened in order to obtain the necessary amount of room. A living fœtus was extracted. The patient passed through this unique experience with satisfactory results as to the healing of the wounds; she is now in good health. Dr. NOBLE does not approve of the performance of any subsidiary operations for the purpose of preventing future pregnancies, as was done in the case of the French surgeon CRIMAIL; he would do nothing to prolong the section, and the deligation of the Fallopian tubes is objectionable, from a theoretical standpoint, as a possible cause for salpingitis. So far as is known to him, the ligature had thus been used only twice. Dr. NOBLE further stated that there had been twelve Cæsarean operations done in Philadelphia in the last four years, and ten mothers had recovered. One of the mothers who died had pneumonia at the time of the operation, and

in the other case of death there was a complication in the fact that the surgeon at the same time removed a fibroid tumor.

ANDROLOGY AS A SPECIALTY.

The first step in the right direction as far as the differentiation of the department of genito-urinary diseases into a separate and distinct specialty, was the formation of the Section of Andrology in the Congress of American Physicians and Surgeons. Much adverse criticism and some ridicule were excited by the nomenclature which the American Association of Genito-Urinary Surgeons constituting this Section finally adopted. But the American Andrological Association—now an important integral part of the Congress—is a complete success, and has demonstrated its ability to place the specialty of andrology upon as high a plane as that occupied by gynecology, ophthalmology, or dermatology. The parallelism between andrology and gynecology is especially well marked. The exigencies of general practice, which finally demanded the establishment of a department of surgery devoted exclusively to the study and treatment of diseases peculiar to women, are well recognized. The crude and imperfect work—and, we were going to say, surgical barbarity—characterizing this highly respectable special branch of surgical art prior to its differentiation into a specialty, are difficult to realize in the light of the magnificent work that is being done in this department at the present day. There is no question but that those affections peculiar to the male have been more neglected, less fully understood, and more frequently treated “for what there is in it,” rather than a desire to benefit the patient, than was ever true of the diseases of women. We believe that to-day fully as barbarous, slipshod, and dishonest work is being done in this class of affections as was ever to be observed in gynecic disease. Diseases of men have ever been the fruitful field of the quack and charlatan, and it must be confessed, that of certain physicians who in other directions, perhaps, may exhibit comparative honesty of purpose and practical skill. They have been the fruitful soil wherein the noxious principles of professional prejudice and popular ignorance have thrived and waxed luxuriant in the development of a crop of error, quackish pre-

tense, and incompetent surgery. Fostered by the indifference and neglect of the respectable physician, the practices of the quack have flourished like a poisonous fungus at the roots of the mighty oak of medical science. It is high time that a special association for the study of andrology should be encouraged by the sentiment of the profession at large. The time will come when the new departure in specialistic practice and nomenclature will be looked upon with quite as much favor as is gynecology to-day.

But andrology will never occupy the position it deserves until the average doctor ceases to think himself competent to treat the most complicated case of genito-urinary disease—as long as the patient's money lasts. There is no part of the body that so quickly and painfully resents incompetency and tinkering as does the genito-urinary apparatus of the male.

PHYSIOLOGY OF VOMITING.

There is no more common symptom of disease, with the possible exception of pain, than vomiting. It occurs in such a variety of conditions both general and local, and is, withal of such importance in the differential diagnosis of many morbid conditions, that clear ideas of the mechanism of its production are a desideratum. Our standard works on physiology present some rather wide discrepancies. FOSTER says that the varying impulses presented in the act of vomiting may best be considered as starting from a centre located in the medulla, near the respiratory centre. LANDOIS and STERLING state that the centre for the movements concerned in vomiting lie in the medulla oblongata. MILLS says that the vomiting centre is usually located in the medulla; he believes, however, that the doctrine of centres in its present form, especially with such precise limitations physiologically and anatomically, cannot be maintained. In this matter, he thinks we have been overlooking the connection of parts while occupied with defining their limits, and it is more than likely that our explanations of the entire process are quite inadequate to unravel its real complexity. HLASKO (Inaug. Dis. Dorpat., 1887) after a large number of experiments, came to the conclusion that there was no centre in the bulb, but that contractions of the cardia were determined by impulses pro-

ceeding from the corpora quadrigemina, the pathway was by the vagus and cord, especially the former. The efferent pathway for contraction of the stomach walls is wholly by the cord. In none of his experiments did any other portion of the brain determine contraction of the stomach excepting the corpora quadrigemina. An inhibitory centre for the cardia was found near the point where the nucleus caudatus joins the lenticular nucleus, not far from the anterior commissure. This dilator nerve forms part of the pneumogastric. It is well known that section of both vagi does not always suppress vomiting, though it makes the act difficult and imperfect. The experiments of HLASKO show that vomiting is absolutely stopped after the destruction of the corpora.

In view of the conflicting results obtained by experiments and the varying views of standard writers, it is too soon to formulate a theory regarding this one of the commonest but least understood of all the ordinary reflexes. Until the physiology of this function is better understood, it is folly to dogmatize regarding those complex disorders, sea-sickness and the vomiting of pregnancy.

VEGETARIANISM.

Numerous experiments have shown that a diet limited to certain articles of food is sure to result in the production of pathological lesions, the result of the malnutrition. These lesions show themselves early or late, according to the foods abstained from, and are tolerably characteristic for some foods or classes of foods. It is to be regretted that our observations have not been sufficiently extensive or definite to foretell accurately what particular symptoms will follow a particular starvation. It is well established that cattle deprived of common salt develop rough, shaggy coats, and later the hair drops out in spots; also that vegetable acid starvation results in scorbutus. The valuable observations of SALISBURY, made some years ago, have not yet met, at the hands of the profession, with the recognition that they deserve.

A note by DR. ALANUS, which has been going the rounds of the journals, has revived an old observation of one of the results of an exclusive vegetable diet, which should be borne in mind.

ALANUS had lived for a long time as a vegetarian, without feeling any better or worse than he had when using a mixed diet, when suddenly, although still under 40, he discovered that atheromatous degeneration was beginning to show itself, being particularly noticeable in the radial and temporal arteries. GUBLER had long ago shown that vegetable food, being richer in mineral salts than animal food, introduces more of these substances into the blood than animal food does, and that its exclusive use was followed by calcareous degeneration of the arteries. RAYMOND has observed numerous cases of atheroma in a monastery of vegetarian friars, amongst others, that of the prior, a man of 32, whose arteries were already considerably indurated. From Bombay and Calcutta, where many people live exclusively on rice, TREILLE, a naval surgeon, has reported many cases of atheromatous degeneration.

The importance of such observations does not lie in their showing the insufficiency of a limited diet, as that is already well known and accepted, but in the indications for feeding which they give in similar cases which develop irrespective of the diet.

THE INFLUENCE OF ONE FEVER ON ANOTHER.

Under this caption, DR. H. NOBLE JOYNT, of the Bradford Fever Hospital, gives some observations which he has made in the course of his wide experience in fever cases.¹ He remarks: "It is the daily experience, and indeed the bane, of every fever hospital physician to see a patient suffering from one fever, develop a second which has been incubating in his system before admission; or when convalescent, contract a fever from some other patient in spite of all precautions." Thus he has seen "mulberry rash of typhus, and the rose spots of enteric well developed at the same time; the erythema of scarlatina forming a brilliant ground for the vesicles of varicella, the dark maculæ of measles and rōtheln, and the rose spots of enteric."

Such observations are by no means new, but it has been the custom to deny that they are due to the presence of two distinct diseases in the individual, at the same time, but to assume that these appearances are more apparent than real, and

¹ Practitioner, XLVII, 261.

merely accidental manifestations of the original poison.

The dictum that but one infectious disease can exist in an individual at a time, has secured an almost universal acceptance, and has even dominated workers in original investigation, and yet it must be admitted that it stands only on clinical ground, and therefore is no more worthy of credence than the opposite view.

Now that it has been established that diphtheria is a local process, which produces its systemic effects through the poisons elaborated at the seat of the lesion, and absorbed therefrom, there can certainly be no objection, even theoretical, to the view of the old clinicians that diphtheria may be engrafted upon any of the infectious diseases.

Certainly the chemical poisons of diphtheria can be absorbed from a mucous surface by a patient affected with an infectious disease, as readily as the medicines administered can be absorbed, and there is no reason why their super-added effects should not be exhibited. When it has been shown satisfactorily just how many and what microorganisms can produce the disease or diseases known clinically as diphtheria, it will be time enough to determine whether the false membranes developed in the throat in scarlatina, typhoid and other diseases, are truly diphtheritic or not.

Why are not many of the symptoms of typhoid fever due to the absorption of poisons from the intestinal canal, intoxication complicating infection?

Concurrent varicella and scarlatina has recently received some attention at the hands of the French.

We have recently seen a child, who in the course of whooping cough, developed a typical enteric fever, during which the characteristic whoop ceased, to return on the cessation of the fever.

It is admitted that clinical evidence alone is not sufficient to establish the concurrence of two diseases, neither is it sufficient to disprove their concurrence. The apparent concurrence of two infectious diseases is not common, but to deny that such an actual concurrence is impossible, is going farther than exact observation warrants.

SOCIETY PROCEEDINGS.

Medical Society of Virginia.

The twenty-second annual session was held in Lynchburg, Va., October 6 to 8. Attendance about 200, including the following from other States: Drs. T. D. Crothers, Hartford, Conn.; A. M. Phelps, New York City; Chas. H. Shepard, Brooklyn; B. A. Watson, Jersey City; Wharton Sinkler, Philadelphia; H. P. C. Wilson, Thomas A. Ashby and J. J. Chisolm, Baltimore; I. S. Stone and Jos. Tabor Johnson, Washington, D. C.; Geo. H. Zimmerman, of Cranberry, N. C.; Geo. T. Vaughan, Surgeon U. S. Marine Hospital Service, at Evansville, Ind.

The President, Dr. Wm. W. Parker, of Richmond, Va., presided, and delivered a most unique, instructive and interesting *Presidential Address* on St. Luke and Jenner as physicians—showing their exemplary characters and pointing out the incalculable good they had done medical science, for which we in this day forget to give them credit.

A large and appreciative audience of ladies and gentlemen, beside members of the Society, was present on the first night to hear the address to the public and profession by Dr. C. M. Blackford, Jr., of Lynchburg, Va., on "*Medical Education as it Was; as it Is; and as it Should Be.*"

This address was followed by a most appropriate paper by Dr. Rawley W. Martin, of Chatham, Va., (who had been specially requested by the State Board of Medical Examiners to prepare it) on the

MISSION AND METHODS OF THE MEDICAL EXAMINING BOARD OF VIRGINIA.

The wonderful effects of the operations of this Board since its organization, January 1st, 1885, upon the education and tone of the Virginia profession; its now universally recognized benefits to the people of the State; its influence in leading colleges outside as well as in the State to do better work, and to require a better standard for graduation, etc., were all commented on. And the remainder of the address detailed the methods adopted by the Virginia Board in conducting examinations, etc. It is a valuable paper for general use.

The committee on examination of essays presented in competition for Dr. Hunter McGuire's prize of \$100, on the subject of "Pyelo-Nephritis," reported that in their opinion neither of the essays presented was entitled to the prize.

The subject for the prize essay next year is *Tetanus*.

Hereafter, in lieu of the usual reports on advances in the several departments of Medical Sciences, the president is to appoint fifteen Fellows, each of whom is to prepare an essay or lec-

ture on some subject of his selection, to be announced in ninety days after adjournment of the session.

After the routine work of the morning session of the second day, Dr. William W. Parker, of Richmond, Va., delivered the "President's Address," which was unique, classic, instructive and most entertaining. It was devoted mostly to a review of the lives of St. Luke and Jenner as model men and great physicians, and showed how much of good to humanity had resulted from their labors as doctors.

ACUTE AND CHRONIC DYSENTERY,

Was the subject for general discussion. The leader, Dr. P. B. Green, of Wytheville, Va., briefly reviewed the literature of the causes, symptoms and pathology of the disease, but devoted the bulk of his paper to the questions of treatment. The "laxative and opium plan," he said has pretty generally fallen into disuse. The "antiphlogostic plan" is admissible only in sthenic cases, which are extremely rare. The "continuous use of large doses of calomel" seems unnecessary. When such doses are "followed by salines," depression is apt to follow. However, one or two decided doses of calomel are indicated if the condition of the patient is "bilious." "The saline laxative plan" is undoubtedly beneficial in the earlier stages of the catarrhal variety. "Castor oil in repeated doses" has warm advocates. The "opium treatment" to the stage of semi-narcosis is unsafe. "Ipecac treatment" is extravagantly commended by many. It is best to administer it in wafers or capsules. Dr. Green, however, has not used ipecac with very satisfactory results. "The antiseptic mode" promises more than any other. Among agents used are iodoform, salicylic acid, cupric sulphate, boric acid, carbon-bisulphide water, creosote, naphthalin, bichloride of mercury, salicylate of sodium, resorcin, etc. Sodium salicylate seems to be the preferred. Beaumetz gives

- R. Carbon bisulphide, \mathfrak{zvi} .
Water, \mathfrak{zxxvi} .
Spts. peppermint, gtt. xxx.—Mix.

Shake well; let settle. Then take 8 to 10 tablespoonfuls, diluted with milk or water, during the day. If the disease continues a week without improvement, the suppurative stage has probably set in. Then an emulsion of turpentine, such as the following, has acted well in his hands:

- R. Tinct. of opium, $\mathfrak{z}ij$ —iv.
Oil of turpentine, $\mathfrak{z}iiss$.
Gum Arabic, (powdered).
White sugar, \mathfrak{aa} $\mathfrak{z}ss$.
Camphor water, $\mathfrak{z}ij$. Mix.
S. Teaspoonful every four to six hours.

Astringents may now be required, such as drugs containing tannic or gallic acid, carbolic

acid, acetate of lead, sulphate or chloride of zinc, and nitrate of silver. If severe hæmorrhage sets in, he uses ergotole or ergot hypodermically. "Treatment by rectal injections" has invariably proved successful in adult cases in his hands, and in most cases of children, except infants. He prefers a fountain syringe, filled with a warm solution of mercuric bichloride (1 : 10,000 up to 1 : 3,000) every six to twelve hours. Immediately after this injection into the bowel, let patient evacuate the bowels, and introduce a suppository of opium. Among other antiseptics so used are salol, Listerine, fluid extract of hydrastis, salicylic acid, the salicylates, etc.

In a paper on the subject by Dr. Wm. J. Crittenden, of Unionville, Va., the frequency of dysentery in both the Union and Confederate armies during the Civil War is commented upon. Along the Pacific coast, its frequency is stated to be in the proportion of 1 : 1,000 deaths from all causes; on the Atlantic coast, 10 : 1,000; along the Mississippi River section, 21 : 1,000. Warm climates furnish the soil for the dysenteric germ. After describing the anatomical and clinical histories of the disease, he spoke of the complications, such as peritonitis, perityphlitis, intussusception, intestinal perforation, liver troubles, etc. He described the various modes of treatment, prophylactic and curative.

Dr. Bedford Brown, of Alexandria, Va., followed with a paper on

DYSENTERY VIEWED AS A SEPTIC DISEASE, AND TREATED PRINCIPALLY BY ANTISEPTICS.

Leaving out of consideration those cases due simply to irritants, etc., he spoke of the septic forms, heretofore designated as malignant, camp, jail, famine, typhoidal dysentery, etc. Foul conditions of food, water or air are the common causes of this septicæmic form. Its mortality ranges from 75 to 25 per cent. Absolute and continuous cleanliness of the drinking-water, of food, and of the air breathed, is the preventive. In the septic form of dysentery, begin treatment with calomel as a cathartic, followed by Epsom salts to thoroughly cleanse the alimentary canal. Then use injections of carbolic acid $\mathfrak{z}ij$ in 2 or more pints of water. This may be followed by an anodyne enema of a drachm of laudanum. Then

- R. Aromatic sulphuric acid, $\mathfrak{z}ij$.
Sulphate of magnesia, $\mathfrak{z}ss$.
Deodorized tincture of opium, $\mathfrak{z}ij$.
Syrup of orange peel, $\mathfrak{z}j$.
Peppermint water, $\mathfrak{z}ij$.
Water, $\mathfrak{z}ij$. Mix.
S. Tablespoonful every three hours.

An occasional full dose of Epsom salts relieves engorgement and corrects the secretions. A more decided antiseptic course is required in severer cases—such as naphthalin, salol and phenacetin, \mathfrak{aa} gr. v, every three hours, and irrigation of the

bowel twice daily with creolin. If adynamia supervenes, with intensely offensive bloody discharges, with mucus, pus, sloughs, etc., hydrogen peroxide—an ounce or two in a pint of water as an injection—is the best antiseptic, or ichthyol dissolved in mucilage. Sustaining diet must be used. If collapse threatens, give $\frac{1}{100}$ gr. each of atropia, strychnia and nitro-glycerine, beside hypodermics of caffeine. In malignant hæmorrhagic forms:

- R. Opium, gr. ss.
 Tannin, gr. ij.
 Strychnia sulphate, gr. one-fiftieth.
 Iodoform, gr. j.
 Creosote, gtt. j. Mix.

S. Repeat every two or three hours. Also give turpentine, $\frac{3}{4}$ ss, in a pint of emulsion.

Chronic dysentery should be considered as due to septic wounds. The septic fæcal matter constantly passing over the wounded surface keeps up the condition. Use simple tepid water irrigations; then use, twice daily, $\frac{1}{2}$ to 1 gallon of solution of hydrogen peroxide, creolin or ichthyol. A soft rubber tube, about 15 inches long, passed into the colon, is the most efficient means of irrigation.

Dr. J. Edgar Chancellor, of the University of Virginia, instanced some remarkable cures of chronic dysentery by the use of the Rockbridge alum springs water.

Dr. R. I. Hicks, of Warrenton, Va., had not succeeded with antiseptic irrigations. At the same time, locking up the bowels with opium had been fatal, although opium is useful to provoke sleep, especially if associated with a suitable laxative. With such treatment, he had thirty-three successive cures; whereas of fifteen cases treated by irrigations, he had one death.

Dr. D. A. Langhorne, of Lynchburg, Va., agreed with Dr. Hicks about irrigation. The calomel purgative treatment is too risky, and opium is positively harmful. Rockbridge alum springs water is especially valuable in those chronic cases having pale, flabby tongue, etc.

Other speakers were Drs. R. M. Slaughter, of Theological Seminary; W. L. Robinson, of Danville; H. M. Nash, of Norfolk; J. S. Apperson, of Marion; J. E. Anderson, of North Danville—all of Virginia.

During the afternoon, the following elections for the ensuing annual term were made: President—Dr. H. Gray Latham, of Lynchburg; Vice-Presidents—Drs. J. R. Gildersleeve, of Tazewell C. H., Hugh Stockdell, of Petersburg, and J. B. Moore, of Aylett's; Secretary—Dr. Landon B. Edwards, of Richmond; Corresponding Secretary—Dr. J. F. Winn, of Richmond; Treasurer—Dr. Richard T. Styll, of Hollins; Chairman Executive Committee—Dr. Hunter McGuire, of Richmond; Chairman Committee on Applicants for Fellowship—Dr. Wm. D. Turner, Fergusson's Wharf, Isle of Wight Co.; to fill vacancies on

Medical Examining Board of Virginia—Drs. Kent Black, of Blacksburg, and Wm. S. Christian, of Urbanna. To deliver "Address to Public and Profession, 1892"—Dr. Jacob Michaux, of Richmond. Subject for General Discussion, 1892—"Vertigo;" Leader—Dr. E. T. Brady, of Marion. Luray is place of session, 1892, during second week in September.

Preceding elections, invited guest Dr. A. M. Phelps, of New York City, operated on two cases of club-foot, and afterwards made a clinical lecture on the subject. His operation on the boy of about 13 years, for a congenital and very disfiguring talipes equino-varus, excited special commendations, as being a most difficult operation well performed, etc.

During the night's session, invited guest Dr. Charles H. Shepard, of Brooklyn, N. Y., read a paper on

THE TURKISH BATH IN THE TREATMENT OF DISEASE.

The essential principle involved in this bath is, "the application of heat in varying temperatures," to quicken circulation and excite perspiration. Manipulation or massage follows the bath. "The Turkish bath is a prime element in preventive medicine," and belongs in the first rank of remedies for rheumatism, malarial troubles, etc. It substitutes climatic influences when they are needed—removing congestion, inflammation, equalizes circulation, and imparts activity to the secretory organs. The paper was favorably discussed by Drs. T. D. Crothers, of Hartford; L. G. Pedigo, of Roanoke; E. T. Brady, of Marion; Geo. W. Hubble, of Chilhowie, etc.

Dr. S. J. Baker, of Bedford City, Va., read a paper on *Pharmacy and its Practical Relations to the Profession*, its scope being set forth in the title.

During Thursday morning's session, Dr. H. P. C. Wilson, of Baltimore, fraternal delegate, etc., read a paper on

RETRO-DISPLACEMENTS OF THE UTERUS.

Retroflexion is the most common, and sooner or later leads to serious symptoms in other organs, as of bladder, stomach, heart, brain disease, etc. Removal of the chronic retroflexion does not promptly relieve the symptoms referred to. Judicial constitutional treatment as well as treatment of the organs which have suffered are essential. To diagnose retro-displacements, empty the lower bowel; pass *left* index finger per vaginam, knuckles down to depress perineum which permits the finger to reach higher. The woman being on her back on a table, with thighs flexed on her abdomen, and legs on thighs, the finger can usually determine whether or not the fundus uteri is back in the hollow of the sacrum. Sim's left lateral position is the best for the use of the probe. Introduce Sim's speculum; steady cervix with tenaculum, and introduce the probe

to determine the amount of fixation, the direction of the uterine canal, etc. If the retro-displaced uterus be of recent duration and movable, it can usually be easily replaced and held in position with a comfortable pessary. In the after treatment, wash out the vagina daily with hot water, and also see that the bowels are opened every day. Constipation is the rule in all these cases. So that he has almost come to the conclusion that the end of woman is to serve God, and keep her bowels open. If the pessary is uncomfortable, remove it at once; but if comfortable, do not remove it until long after its use is deemed unnecessary. When then removed, substitute a smaller one, until the patient can do without any. The pessary should be long enough and sufficiently curved to raise the fundus uteri out of the sacral hollow, and carry it forward to its natural position; but it should not be so wide as to put the lateral vaginal walls on the stretch. When irritability and sensitiveness prevent complete restoration, replace the womb only partially, and hold it so until the wearing off sensitiveness permits its being more perfectly replaced. A pessary is usually required for two or three years. If the vagina chafes or becomes unduly irritated, remove the pessary for the time, introduce Sim's speculum, and touch the abrasion with a weak solution (1:12) of Monsel's solution and glycerine, and use a fresh pad of aseptic lamb's wool till the pessary is re-inserted. Hodges' or Smith's bow pessary are best for retro-displacements.

Invited guest, Dr. Joseph Taber Johnson, of Washington, D. C., remarked that Dr. Wilson's paper was a capital one in all its descriptions. The greatest caution should be urged about the use of the pessary if inflammation exists. If such a condition as a fibroid in the posterior wall causes retro-displacement, of course the pessary will not be sufficient—surgical aid must be summoned. To use the probe simply to determine the course of the uterine canal is harmful in many cases. The womb is intended to be a movable organ; hence to apply a pessary that fixes it in one position will result in injury.

Dr. L. Lankford, of Norfolk, Va., said that in some cases of seemingly extensive and firmly adherent retro displaced uteri, he had done good by first swabbing out the vagina with mercuric bichloride solution (1:4000), and then applying a tampon (about once in five days) of selected lamb's wool wet with the same solution. If required, steady the cervix with a tenaculum while passing the tampon into the uterine cavity. Then throw into the vagina and all over the cervix uteri a powder of iodoform (one-third) and bismuth subnitrate (two thirds). Sometimes he uses boro-glyceride instead of the above. A pessary made of marine lint (which is aseptic) is then introduced.

Dr. I. S. Stone, of Washington, D. C., commended Dr. Wilson's paper for its cautions as to the use of pessary and probe. Various ovarian diseases and peri-uterine inflammatory adhesions are the most frequent causes of chronic retro-displacements; but it is obvious that no pessary can remove such causes. Some patients express themselves as feeling better after the doctor in whom they have confidence does anything looking to their relief. Thus pessaries are often beneficial in the way of favorable mental impression. But when a pessary does not cure in a short time, then remove it and substitute another treatment. He had recently removed a pessary from a lady in whom it was inserted some years previously while she was in Japan. The pessary had most probably excited the growth of the three fibromata which he found attached to the uterine wall.

Dr. R. M. Slaughter, of Theological Seminary, Virginia, reported a case of long wearing of a pessary.

Dr. Wilson closed by emphasizing some of the points he had made.

Dr. H. M. Nash, of Norfolk, Va., presented an admirable review of *Advances in Obstetrics and Diseases of Women and Children*.

Invited guest Dr. Thomas A. Ashby, of Baltimore, presented some personal

OBSERVATIONS ON THE ETIOLOGY AND PATHOLOGY OF THE DISEASES OF THE PUERPERIUM.

In no case of puerperal metritis, peritonitis or septicæmia examined had he failed to find evidence of cervical laceration; the same is true with reference to cases of tubal diseases that had come under his observation. He remarked upon the different morphological characteristics, as well as clinical histories, lesions, etc., produced by the different microorganisms which enter the vagina. The germ of putrefaction produces a distinct sapræmia, while the germ of suppuration develops true septicæmia or pyæmia. Bacteria termo generate ptomaines or leucomaines, which enter the blood and produce putrefaction. On the other hand, micrococci, chain-bacteria or streptococci of wound infection are believed to be identical, as they flourish in the blood and multiply so rapidly as to cause the most profound toxæmia. Thus it will be seen that most of the diseases to which he has referred are preventable by thorough asepsis.

In the paper on

PUERPERAL ECLAMPSIA

by Dr. J. T. Graham, of Wytheville, Va., it was shown from a study of 180 cases that the time honored theory that albuminuria is a cause of puerperal eclampsia is not true in every case. He treated the subject in four divisions. 1. Albuminuria without eclampsia; 2. eclampsia without albuminuria; 3. the conditions of the kid-

neys during pregnancy; 4. the products of intestinal putrefactions. In the first division it was proven from statistics that the majority of cases of albuminuria during pregnancy do not result in convulsions; under the second division it was stated that cases of eclampsia have often been known where no albumin was found in the urine. The theory of obstruction to the free flow of the urine by pressure of the gravid uterus upon the kidneys, their blood vessels and ureters is dwelt on in the third division; but particular attention is called to the fourth division, viz.: *the absorbed soluble products of intestinal putrefactions*. Constipation is the rule in the pregnant woman and putrefaction of the contents of the large bowel is more liable to occur, the products of which are absorbed, more or less, and are poisonous. This is especially dangerous if the kidneys are not active enough to eliminate these poisons from the blood.

The treatment is prophylactic, sedative and eliminative. The first is considered most important. It is suggested that as soon as a woman knows she is pregnant she should be under the care of a physician who should regulate her diet, clothing, exercise, etc., and keep her skin, kidneys, and bowels active. Many physicians are too careless about the examination of the urine of pregnant women. The sedative treatment consists in the use of bromides, chloral hydrate, morphine, chloroform, and veratrum viride. The eliminative treatment consists of diuretics, diaphoretics, hydragogue, cathartics and venesection.

SYMPTOMATOLOGY AND TREATMENT OF CHRONIC FORMS OF NEPHRITIS.

As a summary of the paper by Dr. Wm. C. Dabney, of the University of Virginia on this subject, he itemized the following conclusions:

1. Dropsy is often absent in cases of chronic Bright's disease.

2. The symptoms which, when not clearly due to other causes, should suggest an examination of the urine and cause a suspicion of Bright's disease are: 1. Pallor or a dark color of the skin of the face. 2. Nausea and vomiting. 3. Headache and giddiness, drowsiness, dulness, stupor or convulsions. 4. Disturbances of vision. 5. Paroxysms of difficult breathing.

3. Albuminuria and the presence of casts are not invariable symptoms of chronic Bright's disease, but are often absent in the most serious cases.

4. The amount of solid urine discharged is diminished in all cases.

5. A milk diet and the avoidance of cold and dampness are of the greatest importance in these cases.

6. Digitalis is useful when the flow of urine is scant, and the pulse soft and compressible.

7. Nitro-glycerine is useful when the pulse is full and hard.

8. Nitro-glycerine and digitalis may often be given together with advantage.

CONCUSSION OF THE LUNGS

was the subject of a paper of rare interest by invited guest Dr. B. A. Watson, of Jersey City, N. J. He uses the term "concussion" in precisely the same sense as it is used when speaking of the brain as the seat of the concussion lesions, allowing for differences in the weight and texture of the organs involved. His paper is based on a study of 141 original experiments. He considered his subject under the following subdivisions: 1. An organic disturbance attended with slight pathological lesions, not characterized by any consecutive complications. 2. A severe organic disturbance, attended with severe pathological lesions, characterized by physical and rational symptoms, and commonly followed by consecutive complications which are generally inflammatory. 3. A grave organic disturbance, attended with grave pathological lesions, frequently producing death within a few minutes or a few hours. Indirect concussive force is much more productive of serious lesions in the thoracic, abdominal and pelvic organs than to the brain or spinal cord.

Dr. I. S. Stone, of Washington, D. C., read a paper giving an account of an interesting

MYOMECTOMY FOR PARASITIC TUMOR.

The patient, an unmarried woman of 35 years, had noticed the growth for several months, but was not greatly inconvenienced by its presence. She was somewhat emaciated, had decided albuminuria, and her abdomen gave the appearance of pregnancy at the eighth month. The operation was not particularly difficult, the chief interest lying in the development and attachments of the growth. It had a slender attachment or adhesion to the uterus posterior to the fundus, and this indicated its birthplace. Its diminished nutrition being interfered with at this time, a new base or pedicle was formed on the posterior surface of the right broad ligament. The uterus, tubes and ovaries were quite normal in appearance, and were not disturbed. The pedicle was treated as suggested by Schroeder for hysterectomy, it being too short to fasten in the wound. The patient made an excellent recovery, and continues well.

THE TREATMENT OF GOITRE BY ELECTROLYSIS, was the title of a paper read by Dr. Chas. M. Shields, of Richmond. In the cases reported he used the *labile* method or application of the electrodes to the surface of the skin without puncture.

One of the cases was of the simple glandular form, three of fibro-cystic. All had been treated before by the usual means such as iodides, blisters, hypodermatic injections, setons, etc., without im-

provement. By the means of electrolysis three were cured and the fourth reduced to one-third its original size. The sittings were from two to six days apart, and from fifteen to thirty Leclanche cells.

Dr. W. H. Baker, of Lynchburg, Va., read an interesting and instructive historical paper, giving *A Glimpse of Ancient Egyptian Ophthalmology*.

Dr. Joseph A. White, of Richmond, Va., presented two papers—one on *Mistaken Impressions about so-called Nasal Catarrh*, and one on *Some Suggestions about Cataract Operations*.

Invited guest, Dr. Wharton Sinkler, of Philadelphia, read a paper on *Hereditary Chorea*, and reported three additional cases. He also read the details of an autopsy made in a case previously reported. The result of the examination showed no gross changes in the brain or cord, but microscopic examination of the cord revealed very distinct changes about the central canal and degeneration in the antero-lateral columns.

Dr. William F. Drewry, first assistant, Central Lunatic Asylum, Petersburg, Va., presented a resumé of the progress made within the past year, in

DISEASES OF THE MIND AND NERVOUS SYSTEM.

The literature, during the year, on neurology and psychiatry has been voluminous. Our knowledge of almost every known neurosis has been broadened and made more thorough. Microscopy has accomplished wonderful results. Neurology is in its infancy, so to speak. *Inebriety* is frequently a disease of the nervous system, and if dealt with as such, the results would be far more satisfactory than at present. Heredity has a great influence in causing it, as also many other affections of the nervous system. The treatment, though a difficult problem, should be put into the hands of scientific medical men. It can best be carried out in a well regulated retreat, where suitable employment, exercise, proper medication, etc., could be enforced. Instances of neuroses and psychoses following la grippe had been numerous. Melancholia was frequently a sequel. The author had carefully studied the statistics of general paresis and stated that 3 per cent. of all patients admitted to forty-four insane hospitals in this country in 1890 (representing every section), were cases of general paresis. Males predominated seven to one over females. Negroes very rarely had the disease. In the Eastern, Middle and New England States, the percentage of paretics was 4.2 of all admitted to hospitals during the year named. In the manufacturing districts the paretics constituted about 8 per cent. of cases of insanity. In the Southern States 2.7 per cent. of the insane were paretics. In the Western and Pacific States, 2.1 per cent. No class was exempt from this disease. It was by no means confined to brain workers. The

most prolific causes are alcohol, and general mental and physical overwork. Sulphonal as an hypnotic for the insane, was second to chloral hydrate. It had also been employed with success in the quieting of maniacal excitement, controlling spasms, convulsions, etc. It is useful in many nervous troubles.

Dr. T. D. Crothers, of Hartford, Conn., present by invitation, discussed

THE DRINK PROBLEM FROM A MEDICAL POINT OF VIEW.

The hereditary tendencies to the disease of inebriety were forcibly pointed out. To treat the disease, therefore, is to correct the hereditary tendency. Treat everything as dangerous to man and as criminal which perils human health and happiness. Drunkards and drinkers should be considered as dangerous to others in society, and thus absolutely isolated in hospitals, etc. Give them employment and thus make them pay the expenses of their own support. If then such hospitals cannot be self-sustaining, tax the manufacturer and seller of spirits enough to do so.

Dr. J. T. Graham, of Wytheville, Va., in a paper on *What is to be Done With Our Criminal Insane?* advocated that murderers adjudged insane be confined for a period of years. If guilty, the punishment is light enough; if insane, then they should receive the benefit of hospital treatment. To let an insane murderer loose on the community until after a long period of established cure, is dangerous to the unsuspecting.

Mississippi Valley Medical Association.

Seventeenth Annual Meeting, held in St. Louis, Missouri, October 14, 15, and 16, 1891.

FIRST DAY—MORNING SESSION.

The Association convened in the Pickwick Theatre, and was called to order at 10:30 A.M. by Dr. I. N. Love, Chairman of the Committee of Arrangements.

Prayer was offered by Bishop D. S. Tuttle.

The Address of Welcome was delivered by Hon. E. A. Noonan, Mayor of St. Louis, which was followed by brief addresses on the part of the Missouri State Medical Association, by Dr. W. B. Outten; the St. Louis Medical Society, by Dr. Ludwig Bremer, its President, and appropriate remarks by Drs. Harold N. Moyer, and J. C. Culbertson, of Chicago.

After the report of the Chairman of the Committee of Arrangements, which was an interesting and attractive one, Dr. C. H. Hughes of St. Louis, took the chair and declared the Association ready for the transaction of its scientific work.

The first paper was read by Dr. W. Carroll Chapman, of Louisville, on

THE TOXIC EFFECT OF TOBACCO VAPOR, WITH
REPORT OF CASES.

He said that usually the presence of tobacco poison in the systems of tobacco workers is manifested during the first day or two by violent vomiting, retching, purging and often a state of collapse, after which the system may become injured to it. Occasionally we find one whose constitution, even by contact and time, although there is a certain amount of toleration, refuses to receive it kindly, and emaciation begins, attended sooner or later by such symptoms as the following case illustrates:

Case 1.—Willie C., aged 10 years, was found suffering extreme pain in the abdominal region, with the intensity centering at the umbilicus. Temperature, under the tongue, 100°; pulse 108, small, wiry and irregular; respiration 20 to 22, but irregular—several short, shallow respirations followed by one deep and gasping. Tongue glairy, red appearance and pointed. Patient constipated for the last several days; abdomen flat or rather depressed; urine scanty and slightly colored; skin dry, as were the hands and feet, the latter being a little cold. When near the patient the odor of tobacco was so pronounced that the doctor made inquiries regarding it and learned that he worked in a tobacco steamery and further, that he had slight attacks of similar pains at several different times except of a milder form.

As to the nicotianin, indications point strongly to its being a cause. According to Landerer it occurs only in dried tobacco leaves, and has the odor of that plant; a point strongly in its favor, as that odor was so distinct in every case the author had seen. It would seem further, that the basic substances and fatty acids were causative agents, because authors have proven, by physiological experiments, that these cause contraction of the pupil, dyspnoea, abdominal pains, convulsions and death.

The author directs attention to two factors noticeable in all the cases, namely: the emaciation, and the time each one had followed the occupation, that is, from six weeks to three months. The three cases which he reports had not suffered from the vomiting and retching usually attendant upon young tobacco workers the first day or two. In the other, or milder cases, he neglected to enquire regarding that point.

The toxic effects of tobacco vapor and its treatment was a subject worthy of more consideration than the profession has accorded to it in the past, and he hoped that the next few years, aided by diligent and careful investigation, would place the matter in a more intelligent light.

AFTERNOON SESSION.

Dr. Robert C. Kenner, of Louisville, Ky., read a paper on *The Treatment of Typhoid Fever*, in

which he directed particular attention to the cold bath treatment.

Dr. William Warren Potter, of Buffalo, followed with a paper entitled

PELVIC INFLAMMATIONS IN WOMEN; A PATHOLOGICAL STUDY.

The author affirmed that pelvic inflammations and their residues constitute about one-third of the diseases that gynecologists treated, hence the importance of frequent discussions of all moot questions relating to the subject. He briefly reviewed the anatomical relations of the pelvic organs, calling attention to their enormous blood and nerve supply, which became both their weakness and their strength.

He contrasted the pathology of Bennet (1843) with that of Emmet (1873), and the latter with the teachings of Price, Tait, Hegar and McMurry, of the present age. He referred to the pathological studies of Bernutz and Goupil, of thirty years ago, and affirmed that the observations of the present had served to confirm the correctness of those pioneers.

He next asserted that the pathology of to-day had been established by operative surgery, which had shown that pelvic inflammation begins in the tubes or ovaries, and extends to adjacent structures, through absorption or by contiguity; that it almost never begins in the cellular tissues, but may be carried there through the tubes and ovaries by infections, either specific, puerperal or traumatic. He affirmed that the inflammation was in most cases a peritonitis, intra-pelvic or local in character, and not a cellulitis; that para- and perimetritis were misleading and confusing terms, hence should be dropped; and that the so-called pelvic abscess was a sequence of salpingitis, ovaritis or peritonitis, not a primitive accumulation in the areolar tissue itself.

The tentative management in these cases—rest, counter-irritation, hot sitz baths, vaginal douches, and attention to the digestive organs and general health—resulted in only temporary improvement, or in cure in a very small percentage. Those reported cured were generally, if the history could be known, subject to repeated relapses; and a frequently recurring pelvic peritonitis usually indicated leaky tubes. Electricity, too, had disappointed even its most sanguine advocate, and need not be considered.

In conclusion, he asserted that if these views be accepted, the logical deduction was to watch the early manifestations of the disease carefully, that competent surgical skill be invoked before the damage to important structures becomes too great to justify the expectation of successful operation.

Dr. Geo. F. Hulbert, of St. Louis, read a paper on *The Nervous Equation of Pelvic Inflammation*.

Dr. L. T. Riesmeyer, of the same city, con-

tributed a paper entitled *Pathology and Surgical Treatment of the So-called Strumous Inguinal Lymphadenitis*.

SECOND DAY—MORNING SESSION.

The Association was called to order by President Hughes at 10 A.M.

Prayer was offered by Rev. Dr. S. J. Niccols, of St. Louis.

Dr. Rufus B. Hall, of Cincinnati, Ohio, read a paper on *Complications During and Following Abdominal Operations*.

Dr. Arch Dixon, of Henderson, Kentucky, followed with a paper entitled

GASTROSTOMY FOR IMPERMEABLE STRICTURE OF THE CARDIAC END OF THE ŒSOPHAGUS; RECOVERY; SUBSEQUENT DILATATION OF THE STRICTURE.

On July 14, of the present year, Dr. Thomas W. Taylor consulted him in regard to a patient who was unable to swallow anything save liquid. The patient, Captain S., aged 54, weight previous to difficulty in swallowing, 230 pounds, at the time of examination 156 pounds. Examination by means of œsophageal bougie (smallest size) revealed the fact that complete stenosis of the œsophagus existed at the cardiac end. Repeated trials failed to pass the stricture, and the patient was informed that only an operation, the nature of which was explained to him, could prevent his death from starvation. Operation was declined. Again on July 29, the patient consulted him, and after persistent effort he failed to pass the stricture with the smallest bougie. The patient was requested by the author to go before the Henderson County Medical Society, which held a meeting that afternoon, and be examined. To this the patient consented and again an attempt was made to pass the stricture by a number of physicians present, without success. A statement of the case was made by Dr. Dixon, and the unanimous opinion was expressed to the patient that only an operation could save his life. The patient had by this time grown much weaker and was reduced in flesh to 140 pounds. The operation was consented to and on August 4, at the Home Mission Sanitarium, assisted by Drs. John Young Brown, W. M. Hanna, W. S. Stone, A. J. Lieber, and T. W. Taylor, Dr. Dixon did a gastrostomy after Hecker's method, as follows:

The patient was prepared in the usual way, the field of operation being made as nearly aseptic as possible. Chloroform was administered by Dr. T. W. Taylor. The incision was made four inches long, beginning one inch below the ensiform cartilage and an inch and a half to the left of the medium line; the peritoneum was reached, caught up between forceps and divided the full length of the incision. The index and

the middle fingers were inserted, the transverse colon pushed downward and the stomach reached without difficulty; a fold was caught between the fingers and partially drawn through the wound, where it was held by Dr. Brown, while a careful search was made for the cardiac end and to detect, if possible, any tumor or enlargement which might be the cause of the stricture; none could be discovered. A silver pin was now passed through the fold of the stomach, which was drawn through the wound, a little above the level of the skin, care being taken that the pin pierced the mucous membrane, as suggested by Weir, thus forming a support for the stomach in the wound and serving as a guide when the opening should be made into it to show that the cavity was reached. The pin was about three inches long and rested on the skin on either side of the wound; the peritoneal coat of the stomach was now stitched to the peritoneum by a continuous suture, which on either side of the wound included the skin. The peritoneum above and below was brought together by interrupted sutures, which embraced muscle, fascia and skin as well.

The wound was now covered with iodoform collodion over which iodoform gauze was placed, confined by adhesive strips. The opening into the stomach was purposely deferred until adhesions should have formed. The patient recovered from the effects of the anæsthetic well. There was some pain of a darting character, which was relieved by hypodermic injection of morphia $\frac{1}{4}$ gr., and atropia $\frac{1}{50}$. The operation was finished at 11 A.M. At 6 P.M. temperature was 99; pulse 78. August 5th, temperature 98½; pulse 72. Temperature and pulse remained normal until the morning of August 7th, when the dressing was removed.

A few drops of cocaine were injected into the fold of the stomach which protruded through the wound and the gastrostomy was completed by cutting down upon the pin with a tentone. As in Weir's case, the presence of the pin was a valuable guide in showing beyond question that the cavity of the stomach had been entered. There was no hæmorrhage of moment. The adhesions being firm, the pin was withdrawn and the mucous membrane was drawn up and stitched to the skin. A rubber tube was now passed into the stomach through the opening fitting it snugly. Iodoform collodion was liberally used around the tube and over the abdominal wound. Iodoform gauze folded several times, through which a hole was cut for the tube, came next, covered by a piece of rubber sheeting. Borated cotton held in place by adhesive strips completed the dressing. The tube was kept *in situ* by a thread passed through it above and below, and the thread held in place by adhesive strips. Peptonized milk, one-half pint with a teaspoonful of Mosquera's beef-meal was now injected through the

tube into the stomach by means of a large syringe. An ordinary spring clothes pin was used as a clamp for the tube. Six hours later another one-half pint of milk with the beef meal was thrown into the stomach, the patient experiencing a satisfaction which had not been experienced previously from the use of nutritive enemas. Temperature at 8 P.M. reached 101°. At 10 A.M., August 8th, it had again fallen to normal. The feeding was continued at intervals of six hours, the food being varied in character; chopped meat, eggs, bread, etc., the patient having an aversion to brandy, and would take no stimulant of any character. Improvement was steady and in ten days the patient was out of bed. In two weeks he was walking about the house, and in three weeks was down in the city, a distance of one-half mile from the Sanitarium.

On the 29th day of August, twenty-four days after the primary operation, and twenty-one days after the stomach was opened, Dr. Dixon determined to try dilatation, and was agreeably surprised to find that the smallest size, olive-pointed bougie entered the stomach, passing the stricture without difficulty; a size larger was now used and it passed also without force.

The following day a large stomach tube was passed down the œsophagus, and with little difficulty entered the stomach. Dilatation was continued at intervals of a few days. From liquid food the patient soon essayed some solid food, and on September 10 took his first square meal, which consisted of oysters, broiled beefsteak, coffee, eggs and bread. The patient left the Sanitarium, and he was thinking seriously of closing the abdominal opening, or allowing it to close. On September 23, the patient, who made daily visits to his office, complained again of difficulty of swallowing solid food; especially was there difficulty in swallowing bread. The bougies passed the stricture easily on entrance, but on withdrawal there was a decided hitch, even the smallest bougie was caught slightly when withdrawn. Dr. Dixon at first attributed this to spasmodic action, but the difficulty grew greater and greater, until finally he could no longer enter the stomach by way of the œsophagus with a bougie. Liquids could still be swallowed, and found their way into the stomach. He now determined to try retrograde dilatation, and on September 30, assisted by Dr. John Young Brown, he succeeded in finding the cardiac end of the œsophagus and entering it with a very small bougie a boula. The opening was about the size of a very small shirt buttonhole, and felt much like the meatus urinarius in a girl; it was surrounded by a hard tissue, feeling much like a fibroid. A uterine sound was next properly bent and, with the finger as a guide, passed into the œsophagus; this was followed by a uterine dilator. Slight pressure on the handles opened the blades almost half

an inch, but the patient experienced so much pain that it was deemed best to desist. The following day chloroform was administered and retrograde dilatation was accomplished, first by means of G. Wylie's uterine dilator, the use of which enabled him to enter the orifice with a large-sized bougie (rectal).

Up to this time he had not been able to determine whether the stricture was due to malignant trouble or not, but on passing the finger into the non-dilated œsophagus, a friable, irregular growth was detected, which easily broke down and bled rather freely. A piece of this growth was twisted off by forceps, and was sent to Formad, of Philadelphia, for examination. Since the dilatation the patient has been able to swallow solid food without much difficulty, and has notably improved in flesh and strength, and is able to attend to some business.

The author wished to acknowledge his indebtedness to Dr. Robert F. Weir, of New York, for many valuable suggestions, both in the performance of the operation and in the management of the case afterward, gleaned from his report of a similar case published in the *Medical Record*, July 25, 1891.

Dr. Dixon also exhibited the patient to the Association.

Dr. L. Ch. Boisliniere, of St. Louis, exhibited a new obstetric forceps of his own design.

(To be concluded.)

Golden Belt Medical Society of Kansas.

The regular quarterly meeting of the Golden Belt Medical Society of Kansas, was held in Abilene, Kas., October 8, 1891.

Dr. WILLIAM B. DEWEES, President, in the chair, called the meeting to order at 4 P.M. After the general order of business was passed over, Dr. Ed. E. Hazlett, of Abilene, Kas., read a paper on

NEUROSIS OF THE EXTREMITIES,

and reported the case of Dr. King, of Abilene, first president of this Society, whom he brought before the meeting for inspection, as a great sufferer from what may be termed "Metatarsal Neuralgia," for want of a better terminology. The President suggested that, there being no objection, Dr. J. C. McClintock, of Topeka, kindly consent to examine the case of Dr. King before this Society. No objection being offered, and Dr. McClintock consenting, about fifteen minutes were devoted to the examination, without eliciting any positive evidence of their being any central cause. Thus confirming the diagnosis of Dr. Hazlett, of its being of local origin. The case proved a very interesting one, more especially from the fact that several months ago, Dr. J. N. Ketchersid, of Hope, Kas., assisted by

Dr. Hazlett, and several others, removed about two inches of the posterior tibial nerve without any permanent relief. The paper and the case were discussed at length by Drs. McClintock, Ward, Ross, Lyman, Austin, Ketchersid, Blesh, Gunn, Felty and Curtis.

The Society now adjourned until 8 P.M. Promptly on time the President called the evening session to order, and Dr. G. A. Wall, of Topeka, read an instructive paper on

BLENNORRHITIS MARGINALIS,

which was discussed by Dr. Hazlett opening the discussion, Dr. Wall holding that errors of refraction were much less frequent an exciting cause than text books teach, to which Dr. Hazlett took exception, claiming that in his experience errors of refraction were the most frequent cause.

Dr. J. N. Ketchersid, of Hope, Kansas, read a paper on

MANAGEMENT OF ABORTION,

which brought out quite a flood of discussion, which was opened by Dr. Ward of Topeka, Drs. Lyman, Blesh, Felty, McClintock, Austin, Ross, Gunn, and others.

The subject for general discussion was now taken up, Acute and Chronic Dysentery, opened by Dr. Gunn, of Chapman, Kas. This brought out the experience of every member present, and ipecacuanha, sulphate of magnesia, nux vomica and opium were the chief drugs relied upon. The mode and manner of administration, together with special care of patient, differing somewhat. But cleanliness, rest, air and proper feeding were the chief anchors upon which they relied. By request, Dr. Ward, of Topeka, reported several cases of removal of the uterus and its appendages, successfully, for the relief of suffering incident upon diseased conditions of the same.

The Society adjourned to meet in Salina, Kan., in January.

F. B. BROWN, Secretary.

NECROLOGY.

The death of Dr. Thomas A. Rodger, of the Montreal General Hospital, and Chief Medical Officer of the Grand Trunk Railway, is believed to have been the result of pyæmic infection consequent upon his hospital work. In May last, his trouble began as an erysipelatous attack, locating itself upon an apparently slight abrasion. A severe phlegmon of neck and face followed, which led up to a slow pyæmia with suppurating joints, and finally pneumonia. His death, despite the best efforts of the best talent of Montreal, took place after three months of suffering, a premature sacrifice while in the line of duty, at the age of forty-four. He had been president of the Medico-Chirurgical Society, Fellow of McGill University and member of Provincial Medical Board.

EDWARD WILD, M.D.—The death of General Edward Wild, M.D., a graduate of Harvard University and Jefferson Medical College, is reported by telegram to have occurred in South America. His was a remarkably eventful career, in which adventure was more prominent than medicine. When the Crimean war broke out he entered the Turkish army as a surgeon. And about four years after his return home, our own civil conflict occurring, Wild took a commission as Captain in the First Massachusetts, May, 1861. Twelve months later he was chosen Colonel of the 35th, and one year later still he was Brigadier-General, in which capacity he served through the war. Brookline, Mass., was his home, and his membership in the State Medical Society is registered as from that town, in 1850. He was latterly much interested in mining, and it was in part these interests that led him to Medellin, Columbia, where his death took place. He was 67 years old.

DR. JAMES HENRY BENNET, of London and Mentone, died at the latter place, aged seventy-five years. He was formerly physician to the Royal Free Hospital and Western General Dispensary. His "Practical Treatise on Inflammation of the Uterus and its Appendages," reached its fourth edition in 1861, and other publications of his on consumption, hygiene and the health resorts of the Mediterranean were among the most popular of their kind. He was himself a sufferer from pulmonary mischief, and beginning about 1859 spent his winters away from London, generally in the Rivas.

MISCELLANY.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from October 17, 1891, to October 23, 1891.

Major Peter J. A. Cleary, Surgeon U. S. A., upon being relieved from duty at Mount Vernon Bks., Ala., is ordered to duty at Ft. McPherson, Ga.

Major John C. G. Happersett, Surgeon U. S. A., upon being relieved from duty at Ft. McPherson, Ga., is ordered for duty at Ft. Custer, Mont.

Major Richard S. Vickery, Surgeon U. S. A., is relieved from duty at the Army and Navy General Hospital, Hot Springs, Ark., and ordered to duty at Ft. Monroe, Va. Major Curtis E. Munn, Surgeon U. S. A., upon being relieved from duty at Ft. Monroe, Va., is ordered to duty at Mt. Vernon Bks., Ala.

Capt. Edwin F. Gardner, Asst. Surgeon U. S. A., will proceed from Ft. Porter, N. Y., to New York City, for temporary duty as attending surgeon and examiner of recruits in that city.

Capt. Charles M. Gandy, Asst. Surgeon U. S. A., granted leave of absence for fifteen days, to take effect on final adjournment of Army Medical Board, now in session in New York City.

First Lieut. Benjamin Brooke, Asst. Surgeon, is relieved from duty at Ft. Riley, Kan., and ordered to duty at Ft. Leavenworth, Kan.

First Lieut. Frank R. Keefer, Asst. Surgeon U. S. A., upon being relieved from duty at Ft. Leavenworth, Kan., is ordered for duty at Ft. Riley, Kan.

Major Passmore Middleton, Surgeon U. S. A., will report in person to Col. Melville A. Cochran, Sixth Infantry, President of the Army Retiring Board at Newport Bks., Ky., for examination by the Board. By direction of the President.

Capt. Arthur W. Taylor, Asst. Surgeon U. S. A., will report in person to Col. John Mendenhall, Second Artillery, President of the Army Retiring Board at Ft. Adams, R. I., for examination by the Board. By direction of the President.

Capt. Daniel M. Appel, Asst. Surgeon U. S. A., is granted leave of absence for one month, to take effect about 6th prox.

Major William E. Waters, Surgeon U. S. A., upon being relieved from duty at Ft. Custer, Mont., is ordered for duty at Columbus Bks., O.

First Lieut. Nathan S. Jarvis, Asst. Surgeon U. S. A., is relieved from duty at Ft. Bayard, N. M., and ordered for duty at San Carlos, Ariz.

Capt. Richard W. Johnson, Asst. Surgeon, upon being relieved from duty at San Carlos, Ariz., is ordered for duty at Ft. Bayard, N. M.

ORIGINAL ARTICLES.

CLINICAL NOTES ON LICHEN PLANUS.

Read in the Section of Dermatology and Syphilography, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY L. DUNCAN BULKLEY, A.M., M.D.,
OF NEW YORK, N. Y.

PROFESSOR OF DERMATOLOGY AND SYPHILIS, NEW YORK POST-GRADUATE MEDICAL SCHOOL, ETC.

Although lichen planus is one of the more rare diseases of the skin, it is one which occurs frequently enough to warrant the general practitioner being well acquainted with its natural history and therapeutics, while the very considerable suffering sometimes caused by the eruption, and its occasional rebelliousness to remedies, demand a further study from the specialist in regard to its nature and treatment. It is with a view of aiding in both these directions, that I have ventured to bring before this Association the experience which I have had with the disease during the past twenty years.

Erasmus Wilson¹ was the first to call attention to lichen planus, over twenty years ago, and his description of the eruption was so clear and graphic that it was at once recognized, especially in this country and England, and has long found a place in most dermatological classifications; and repeated reports on its clinical features have established them so clearly that, in this country at least, it is now one of the best known eruptions of the skin in dermatological practice. As the description given by Mr. Wilson, in one of his earlier papers, is very lucid and complete, I may be excused for quoting it somewhat at length:

"Lichen planus is an eruption of pimples remarkable for their color, their figure, their structure, their habits of isolated and aggregated development, their habitat, their local and chronic character, and for the melasmic stains which they leave behind when they disappear.

"The color of the pimples is of a dull crimson-red, more or less livid, and suffused with a purplish or lilac tinge. It is most characteristic in

the recently developed and discrete papules, and in the aggregated form is apt to assume the dusky hue of ordinary chronic affections of the skin. The striking color of the papules contrasts very strongly with the unaltered complexion of the skin on which they are developed. Indeed, it is generally the color and appearance of the pimples, without other symptom, that first attracts the attention of the patient to the disorder, and urges him to seek for relief.

"In figure the papules are flattened, smooth, and depressed on the summit, angular in outline, only slightly elevated, and of a size ranging between 1 and 3 lines in diameter. And this peculiarity of figure is so striking that we have selected it as the pathognomonic characteristic of the eruption. The redness may be the first sign to strike the eye, but redness is a phenomenon common to many eruptions of the skin; although, as we have just said, the redness of lichen planus is peculiar, whereas the flatness of the summit of the papules is altogether different from anything that is met with in other affections of the skin; and the flatness is rendered more conspicuous by the summit of the papule being occupied by a thin, horny, semi-transparent lamina of cuticle, depressed on the surface, and marked in the centre by the aperture of a follicle, which represents a sort of *hilum*. It is to this peculiarity of figure that the word *planus* is especially applicable, and this has guided our use of the term."

Lichen planus is rather an easy eruption to diagnose if these peculiarities are borne well in mind, for, as far as I have observed the disease, there are always primary lesions to be discovered somewhere, generally at the edge of the eruption, however old or altered it may be in character; and these primary lesions will always present the flat summit, with the depression in the centre.

In some instances, plaques of considerable size are formed by the aggregated papules of lichen planus, and especially on the lower legs these patches will, at first sight, be not at all suggestive of the eruption in question, but will resemble a dry, hard patch of eczema, of a purplish brown color, with adherent epidermal covering. But on closer inspection, the edges of

¹ Wilson, *Diseases of the Skin*, sixth edition, London, 1867, p. 190.

² Wilson, *Journal of Cutaneous Medicine*, Vol. iii, London, 1869, p. 117.

the patches are seen to be very sharply defined, and abruptly raised, quite differently from anything seen in the latter eruption, and every lesion will be found to have the flat summit characteristic of the disease. The form of the lesions has been likened to an inverted flower pot, only not proportionately so high, with the steep edges, and the hole in the centre, making the *delle* or depression seen in the papule of lichen planus.

The location of the eruption, or its seat of predilection, is also rather peculiar or characteristic. It is pretty constantly met with about the wrist, either on the flexor or extensor surface, and a few or many papules develop on the back of the hands. The next most frequent locality is on the lower legs, especially on the anterior aspect, and commonly it comes on the body only after there has been a considerable development on the extremities. In rare cases it attacks also the palms and soles, and still more rarely the face; it has also been observed by Wilson and others on the tongue, and in one of my cases which was very severe and general, the tongue and buccal cavity were badly affected, giving rise to great suffering. Some years ago,³ the present writer reported two cases of lichen planus where the eruption developed on the glans penis some weeks before appearing elsewhere, when it attacked the usual parts and presented characteristic appearances.

There is still another rather remarkable characteristic of the eruption of lichen planus, which is, that the papules or patches generally leave behind them a pigmentation much greater than would be ordinarily expected from such lesions; and this staining is measurably proportionate to the duration of the eruption or of the individual portions of it. In some instances the discoloration will be of a deep brown, and may persist weeks or months. In other instances it may be very light, and quite transient, but it is always a recognizable feature.

Much difference exists, in different cases, in regard to the subjective symptoms in lichen planus. In some cases, mild in character, there will be very little itching, and the eruption will give little inconvenience except from its appearance, while in certain cases the burning and itching attending the eruption are so severe that the sleep is greatly broken, and the suffering occasioned is excessive. Between these there may be all degrees of inconvenience, but in the main the disease is not characterized by much itching; the single papules appear from time to time, often unnoticed until seen.

Lichen planus, as before remarked, is one of the rarer diseases of the skin, and in statistics from a large number of cases, stands far down the list in regard to its relative frequency. In

my experience, among something over 10,000 cases of skin disease in my clinics at the New York Hospital, and the Skin and Cancer Hospital, there occurred forty-five cases of lichen planus, giving a percentage of .45. Among something over 7,000 skin cases in private practice, of which I have record, there have occurred forty-six cases of lichen planus, giving a percentage of a trifle over .65. The slightly larger relative proportion in private practice is probably accounted for largely by greater attention which would be paid to such an eruption among the wealthier classes, where the disfigurement would call for relief, even if the itching were not troublesome. The combined statistics from these two classes of patients give a total of ninety-one cases of lichen planus among some 17,000 cases, or over 53 per cent. The following table I shows the ages and sex of the cases:

TABLE I.—AGES OF PATIENTS WITH LICHEN PLANUS.

AGE.	Private Practice.		Public Practice.		Grand Totals.
	Males.	Females.	Males.	Females.	
3 years	1	...	1
15 to 20 years	1	...	1
20 to 25 years	1	2	5	3	11
25 to 30 years	4	...	1	2	7
30 to 35 years	1	1	1	3	6
35 to 40 years	5	3	2	3	13
40 to 45 years	3	3	1	5	12
45 to 50 years	4	5	5	1	15
50 to 55 years	3	5	4	5	17
55 to 60 years	2	2	...	1	5
60 to 65 years
66 years of age	1	1	...	1	3
	24	22	21	24	91

The eruption affects males and females in almost the same proportion, there being forty-five males to forty-six females. It will be further seen from this table, that the eruption is one of adult, or rather middle life, fifty-seven of the cases, or 62 per cent., coming between the ages of 35 and 55 years. There were but two patients under 20 years of age, both males, in public practice, and few after 55 years of age. Curiously enough, there were three patients with the eruption who were just 66 years of age. It is a little peculiar that all but two of the twenty-two females seen in private practice were married, and seven out of the ten females seen at the New York Hospital were also married. I have not the data in regard to the fourteen females at the Skin and Cancer Hospital, nor can I learn the marital relations of the male patients. I can hardly believe that this can have any influence in the disease, but it may be a clinical fact worth noting. The two unmarried females were aged 23 and 56 respectively.

Lichen planus has, as far as I know, no tendency whatever to spontaneous recovery. The following table II gives the duration of the disease, before coming under my observation, in forty-eight cases of lichen planus in private and

³ Bulkley, Archives of Dermatology, New York, Vol. vii, 1881, pp. 135, 392.

public practice. Many of the cases had been under other treatment; some had been entirely neglected.

TABLE II.—DURATION OF LICHEN PLANUS IN 48 CASES AT THE TIME OF APPLYING FOR TREATMENT.

Unknown.	1	1	2
Total.	24	24	48

Here we see that while in a considerable number of them, the disease had lasted but a few months, there were some of the patients who had had the eruption a year or more, while in three instances it had remained between five and ten years.

Lichen planus is also rebellious to treatment, as is shown by table III, which exhibits the length of time during which forty-six patients with the eruption were under observation and treatment.

The *prognosis* of lichen planus, therefore, although good as to an ultimate cure, if proper treatment is faithfully carried out, should always be a guarded one in regard to the duration of the eruption, for under the very best of treatment the eruption may persist for weeks, or even months, and even under the best circumstances, seldom disappears very rapidly.

The *diagnosis* of ordinary cases of lichen planus should not be very difficult, if due regard be paid to the peculiar and almost pathognomonic features of the eruption which have been already mentioned; and, as before remarked, some of the primary lesions, quite characteristic in appearance, can usually be discovered in every case, if sufficient diligence be exercised.

The only eruptions which should ever be mistaken for lichen planus are, a newly developing psoriasis punctata, a papular eczema, a lichen simplex, scabies, a papular syphilide, and erythema papulatum.

Some time ago, Mr. Jonathan Hutchinson⁴ described this eruption under the name of lichen-psoriasis, and the mistake of confounding lichen planus with psoriasis is the more justifiable, because, as he has pointed out, the lesions of the latter, when they are just developing, present minute punctate spots, with a shiny summit, like those of lichen planus; and only this morning I saw a new case of the eruption under consideration, which had just been diagnosed as psoriasis punctata by the family physician. As this case is one of very considerable interest, and as it makes the fifth case in which the eruption has developed largely on the glans penis, I may be excused for mentioning it somewhat in full.

Mr. H., aged 28, a strong, well developed and healthy man, with dark complexion and weighing 150 lbs., has never had any eruption before; nor, indeed, suffered from any illness. He never touches spirits or beer, but smokes ten to fifteen cigars daily. Three or four months ago, without any apparent cause, some papules developed on the right arm, on the anterior aspect, just below the bend of the elbow. The number increased every day, and one week later some similar papules appeared on the left forearm in the same situation; their number then increased in both localities up to about a month ago, the new ones coming both on the upper arms and down towards the wrists, and more lately a few small spots have appeared on the backs of the hands. About a month after the first appearance on the arms, similar points developed at the root of the neck, and soon formed several groups, extending along toward the shoulders. All of these papules have remained from the first, and at about the same size, seldom increasing to more than 2 or 3 millimetres in diameter, and not changing at all after they have become fully developed.

About a month after the first appearance of the eruption on the forearms, some points developed upon the glans penis, which increased in number and coalesced, forming patches 5 to 8 centimetres in diameter, of irregular shape, covering half the glans, and also many on the foreskin; these also have remained in much the same condition for the past month. There was little itching with the development of the eruption, but now he experiences considerable discomfort therefrom, especially at night, and particularly on the penis.

The cutaneous condition may be thus briefly described: On the anterior aspect of the upper arms, and the radial side of the forearms, there is an eruption, more pronounced about the bend of the elbow, composed entirely of flat, pinkish-red papules, many of them touching one another, but in no place making anything of a patch. The papules are of quite uniform size, but some of them a little irregular or star-shaped, and with a glazed summit, but nowhere surmounted by a

⁴ Hutchinson, Clinical Lectures on Rare Diseases of the Skin.

perfect scale. Some of them show marks of scratching, and have a more inflamed, red surface, covered with dried exudate. On the flexor surfaces of the left forearm are two very marked papules of large size, sharply defined, and more red than the others; these have been there almost from the first. On the backs of the hands there are a few scattered, red papules, similar in character to those seen elsewhere, most of which are dellated or slightly depressed in the centre.

On the glans penis the eruption, which covers half of its surface, is composed of slightly raised, purplish patches of various sizes and shapes, hard and slightly scaly on the surface, and giving a rather leathery sensation when handled. The prepuce, extending to nearly an inch when retracted, is about half covered with irregular papules and streaks, of a brownish purple, made up of similar papules, also somewhat scaly on the surface; as before stated, the eruption on the organ has remained about the same for a month. There is as yet no eruption on the legs, nor elsewhere than mentioned.

In a guttate psoriasis, which might affect almost the same extent of surface on the forearms, we would have the newly formed papules covered with a more silvery, easily detached scale; the color also would be more livid, and they would not be so decidedly flat and depressed in the centre. Moreover, in this particular case, the diagnosis from psoriasis could be made with certainty by the clinical history, for no psoriasis could remain, as this had, during three months in the same condition; for we know that the papules of psoriasis, which begin very small, invariably enlarge quite rapidly, and in this time would have presented, somewhere, typical lesions of the disease.

Lichen planus is sometimes rather difficult to differentiate from papular eczema and ordinary lichen simplex. But in both of these the papules are more acutely inflammatory, are always acuminate, and never flatten down so as to present the appearances described as characteristic of lichen planus; moreover, these eruptions are more violently itchy from the first, than is that under consideration.

The scattered papules of scabies, sometimes seen on the forearms and about the elbows and abdomen, may suggest lichen planus, but they resemble those of eczema more in character, and the diagnostic marks of scabies elsewhere should establish the diagnosis.

A newly developing papular syphilide sometimes resembles the eruption of lichen planus; but the eruption is more general from the first, while, as we have seen, lichen planus comes out slowly, it being commonly localized in one place for some time before appearing elsewhere. Moreover, the papules of the syphilitic eruption are never so flat and shiny as those of lichen planus, nor have they the central indentation, and the

scale which soon forms on their summit is very characteristic, being of a yellowish brown, attached in the centre, with the edges tending to become loosened. The general and other signs of syphilis will also commonly serve to prevent this mistake.

Erythema papulatum, coming as it very frequently does, about the extensor, and also flexor, surfaces of the wrists, does sometimes suggest lichen planus very strongly. But the papules of this eruption are much larger, as a rule, more elevated and rounded on the summit, and have not the peculiar purplish-pink lustre which can generally be found on the papules of lichen planus. Moreover, the lesions of erythema papulatum commonly come out very quickly, present much more inflammatory character, and subside much more quickly than do those of lichen planus.

For some years past there has been more or less discussion among dermatologists, in this country and abroad, respecting the relation between, or rather the identity of, the *lichen planus* as here described, and as we know it here and in England, and the lichen ruber, as it was so graphically described by the elder Hebra, in Vienna, twenty or more years ago. The subject is an important one, both as affecting prognosis and treatment, but it is also an intricate and difficult subject to discuss, and one which cannot, with profit, be entered upon on the present occasion. It was very thoroughly discussed, both from its clinical and histological aspects, by Dr. A. R. Robinson,⁵ of New York, some time ago, and as his views coincide wholly with my own, I cannot do better than to give you his brief but convincing conclusions, as follows:

"From a comparison of the symptoms, histology, prognosis, and treatment of the two forms of eruption, we find that as regards the symptoms: in lichen ruber the papules generally commence on the trunk, and tend to extend over the entire body, and in lichen planus they generally commence on the forearms and legs, and very rarely spread over a large area. In lichen ruber the papules are round, acuminate, covered with thin scales, and only show a depressed centre when situated around a hair follicle or undergoing a retrograde process; in lichen planus the papules are mostly angular in outline, generally umbilicated, and never scaly at the commencement. In lichen ruber the eruption is not symmetrical, and the papules do not increase by growth at the periphery; in lichen planus the eruption is generally symmetrical, and many of the papules increase in size to a certain extent by spreading peripherally. Lichen ruber, if not treated, tends to marasmus and death; lichen planus has no special effect upon the general condition of the system.

⁵ Robinson, Lichen Ruber and Lichen Planus. G. P. Putnam's Sons, New York. 1883.

"From microscopical observation we find that lichen ruber is an atypical keratosis, and lichen planus an inflammatory affection of the papillæ of the upper portion of the corium, with subsequent changes in the epidermis. In lichen ruber the corneous layer is hypertrophied, the rete also slightly thickened, whilst there are few or no changes in the cutis; in lichen planus the corneous layer is often absent, the rete is thickened, and there is a dense round cell collection in the papillæ and upper part of the corium. Lichen ruber is, therefore, an anomaly of growth of the corneous layer, and lichen planus an inflammatory affection of the vascular portion of the skin." He also argues, very conclusively, that the two eruptions are also not two forms of the same disease, nor are they different stages of the same eruption, and I may say that, being more or less conversant with lichen planus in Vienna, and also with certain rare cases which have occasionally been met with in this country, I am myself most thoroughly of the opinion that lichen ruber and lichen planus are radically two entirely distinct diseases.

I had hoped to be able to give details of some very interesting and severe cases of this disease which have been under my care, but this paper has already exceeded the limits I had proposed to read, and will defer their presentation, but will make a few comments on the general features of the disease, as they have presented themselves, especially in private practice.

I have been constantly impressed with the observation of the far greater severity, and also obstinacy, of the eruption, in women than in men. In looking over my notes of the eruption in the latter, I find very few instances where the eruption was very general, and hardly any one where it caused what could be called any very great distress. But among the female cases I find a dozen cases in whom the eruption became very general, and in nine or ten of these, the suffering from the disease was very great indeed. In one of them the eruption had lasted two years before she came under my care, and another lady had suffered fifteen months. In several of these cases it was necessary to make use of internal quieting remedies in order to get any rest at night. I have also been struck by the fact that, in most of the cases in females, in private practice, certainly those who have had the eruption at all severely, the sufferers had been accustomed to the very great use or abuse of water on the skin, in the way of cold daily general ablutions, so that of late I have inquired into the fact, and seldom fail to find this to be the case. As this is a more common custom among females than males, in this country at least, I have been led to believe that it is an element of causation to be taken into account; and in a number of the cases occurring in males I have found the same habit to prevail.

Occasionally, even a quite severe eruption will disappear very shortly under but very moderate treatment, and in one instance a very general eruption, on a lady aged 52, vanished very shortly after her single visit, and apparently without the aid of treatment; but this is a great exception. In one instance an eruption in a gentleman which had resisted pretty faithful treatment, disappeared under the employment of the cuticula remedies after he had ceased attendance; but, on the other hand, I find notes of other cases where these remedies had been tried in vain before coming under my care.

In regard to the *treatment*, inasmuch as we know very little as to the real causation of the disease, it is very difficult to give an intelligent explanation as to the lines to be pursued. The patients generally appear to be in good general health, and there is very little to take hold of in the way of rectification of supposed errors. We know, however, that the eruption is of a congestive and inflammatory nature, and it appears to be due to a suboxidation process closely akin to that found in eczema and other inflammatory diseases of the skin; and practically this line of treatment is that which is found to yield the best results—indeed, when faithfully carried out, this is commonly very satisfactory.

The alkalis, given with a free hand, will not only serve to mitigate the suffering of the patient, but arrest the further development of the eruption; and of these, acetate of potassa, with nux vomica and a bitter infusion, after meals, have served me about the best. Constipation must, of course, be carefully avoided.

An empiric sort of a prescription was suggested by the elder Bœck, of Norway, when in this country some years ago, and was strongly recommended by Taylor,⁹ in his clear and practical article on the disease some time since; and this has also done me most excellent service in many cases. It consists in the administration of from 10 to 20 grs. of chlorate of potassa, dissolved in considerable water, directly after each meal, followed in half an hour by 20 drops of dilute nitric acid, also well diluted. It was supposed to act as an oxidizing agent, promoting the assimilation of food, and the disintegration of effete substances.

After a cooling course with one of the above, a more tonic course is often required, and then nothing is better than the sulphate of iron, with sulphate of magnesia and sulphuric acid, in what is known in the dermatological world as Startin's mixture. Arsenic, in my hands, has been of very little use in this eruption; indeed, in the more acute stages, seems to aggravate the eruption.

In regard to diet, very little can be said, for we know so little of the causes underlying the eruption. But as it is an inflammatory affection, and associated more or less with a deficient oxi-

⁹ Taylor: Archives of Dermatology, Vol. I, No. 1, 1875.

clation process, the diet should be simple and nutritious, avoiding entirely stimulants and all food of difficult digestion, and also articles liable to undergo acid fermentation. Excess of sweets certainly has seemed to aggravate the eruption in my experience.

Locally, considerable can be done by properly directed measures, both in the way of relieving the general suffering and checking the disease.

In acute cases, the well-known calamine and zinc lotion, with an extra proportion of carbolic acid, certainly gives great relief, and seems to check the development of the eruption.

Ichthyol, in a 2 to 4 per cent. watery solution, kept freely applied, is also grateful and beneficial. When the skin becomes at all dry, a 1 or 2 per cent. carbolized vaseline, freely applied, is the best application.

In more chronic conditions, or when the eruption remains quite localized, the treatment suggested by Unna will sometimes seem to produce a remarkable result. This is a diachylon ointment containing even as high as 4 per cent. of carbolic acid, with bichloride of mercury added in slowly increasing quantity, beginning with 2 grs. to the ounce I have, in rare cases, seen the amount of the corrosive chloride increased gradually, until the patient bore well even 10 or 15 grs. to the ounce. This is of course a great exception, and this plan of treatment should be used with caution, although, when intelligently carried out, it certainly removes the chronic, obstinate lesions, more certainly than almost any other.

Alkaline baths are often of much service in this eruption, and may be taken two or three times weekly, followed by the calamine and zinc lotion, or the carbolized vaseline. On the other hand, as already mentioned, it has strongly impressed me, especially in regard to my cases in private practice, that too great bathing of the skin, especially cold bathing, has been often one of the chief features of causation of the eruption. I have also seen Turkish and Russian baths greatly aggravate the eruption. Sulphur vapor baths are certainly harmful, in my experience.

In conclusion I may say that, although lichen planus is a comparatively rare disease, still, like its first cousin, psoriasis, it is well worthy of careful study; for when recognized, and properly treated, it is curable, whereas, if neglected, it tends to remain and increase often to the very great distress and discouragement both of the physician and patient.

OLEO RESIN of male fern is best exhibited in combination with potassium bromide to secure the expulsion of the tape worm. The object is to reduce peristaltic action.

EARLY PSYCHICAL SYMPTOMS OF TRAUMATIC BRAIN INJURIES.¹

Read before the Section on Medical Jurisprudence and Neurology at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY T. D. CROTHERS, M.D.,

OF HARTFORD, CONN.

The department of neurology in the practice of medicine has attained such proportions that it would be almost impossible in the limits of a single paper to give any complete history of the advances of even one year.

In this country there are six large journals devoted exclusively to this branch. Five quarterlies and one monthly, viz: *The Journal of Insanity*; *The Alienist and Neurologist*; *The Journal of Psychology*; *The Journal of Mental and Nervous Diseases*; *The Journal of Inebriety*; and *The Review of Insanity and Nervous Diseases*.

Abroad, the periodical literature is more voluminous, and books and pamphlets follow each other rapidly. A neurological library of to-day, to be complete, would number thousands of volumes and pamphlets.

This would be exclusive of the literature which appears in the general journals, comprising records of cases, theories, and discussions of diseases of the brain and nervous system.

The different fields of neurology have been studied until the specialists find it almost impossible to master more than a single phase of the subject. The lunacy specialists, the specialists of nervous diseases, the specialists of alcohol and drug diseases, the specialists of idiocy and congenital diseases, the experimenter and teacher of psychology, and the electrician are all examples.

The unknown regions of the physiology and pathology of the brain and nervous system are attracting an increasing number of most ardent students, and already the discoveries are very numerous and startling, and the process of learning and unlearning is more and more difficult. In the department of *Medical Jurisprudence* progress and change is less rapid. Seven medico-legal societies and one large quarterly present the many practical topics which are constantly appearing.

The confusion of theory and practice in both law and medicine, relating to questions of crime and responsibility, has given rise to many strange conceptions of the teachings of science. Thus, from the text books and legal rulings of judges, the lines of sanity and insanity are laid down as absolute facts. Free will, and accountability, judgment, punishment, equity, with brain control and capacity, are regarded as settled facts, based altogether on theory. All these questions comprise a realm of the densest superstition and error that will continue until studied scientific-

¹ Address by the Chairman of the Section.

cally. To-day the student of medical jurisprudence must pursue his studies above all present theories, text books and rulings of law. The questions of motive and human conduct must be decided from a knowledge of natural laws of physiological and psychological growth.

Science calls for a great revolution and evolution in the medico-legal solution of many of the disputed questions of to-day. The insane, the inebriate, the defectives of all grades and conditions, and the tramp and criminal, can never be restrained or prevented from being sources of peril to all law and order, on theory, or metaphysical abstractions of mind, or legal rulings.

Medical jurisprudence of the future must depend on the progress of scientific medicine.

Both neurology and jurisprudence are largely influenced by the neurotic element of American civilization. This is a tremendous factor in degeneration and disease, and enters into all degrees of life and living.

The family physician and general practitioner are most favorably situated to become the earliest and most accurate students of most of those confusing problems in neurology and jurisprudence.

Every year it is more and more apparent that the failure to recognize the early symptoms of brain degeneration and disease, constantly increases the army of incurables. The crowded insane asylums, alms-houses, jails and hospitals, all refer back to early neglect, and failure to recognize and apply the means of prevention and cure.

A clearer knowledge of neurology would point to conditions and methods of treatment that could be successfully applied at that time only. An outline view of some of those early stages is the central topic of this paper.

There is probably no one disease more often mistaken in its early stages than general paralysis. Even after the symptoms have become apparent, there are confusing halts, and a delusive masking of symptoms that often puzzles even experts. A long formative stage precedes the well-defined symptoms, beginning in slight changes of conduct and character, elation of spirits, increased activity of the intellect; the disposition, the manner, the temper, the habits, and general character all become altered. Then come acts and words which are unusual, the friends and associates are conscious of some change which they seek to remedy by moral advice. Finally, when some reckless conduct or strange disposition is manifest, the physician is called and the disease is clearly made out. To the patient this has no foundation in fact, and sometimes the physician joins in this belief, and explains these changes of mind and conduct from some moral basis. Symptoms of alcoholic and sexual excesses are explained in the same way. After a period extending over months and years

in many cases, the disease is above all question, and beyond all medical skill. This formative stage has been attended by distress, loss, sorrow and most serious blunders. In some cases, criminal acts and sad domestic and pecuniary afflictions have marked this period. If the family physician had made an early diagnosis, and the treatment been based on this, a different history and result would have followed.

Some of the ataxies have a similar obscure, early stage, marked by psychical disturbances which are regarded as moral lapses. Nearly all forms of insanity begin with this obscure failure of the high brain centers. Early changes of temper, conduct and character, defects of emotional control, defects of reason, slight and obscure at first, and yet clearly the oncoming shadows of diseases that should be anticipated and pointed out.

These changes and early symptoms are not new to science, but in most cases, they are overlooked and seldom receive the attention they deserve.

There is a class of symptoms that are already becoming the center of serious controversy. They are not only not recognized in the early stages, but are sharply disputed by both laymen and physicians. I refer to the alcoholic, opium and other drug symptoms, which are affirmed to be purely vicious acts and the voluntary giving way to the lower animal impulses. Public opinion has sought to control them by fine and imprisonment. The medical profession accepts this theory of treatment, only asserting after a time, the use of these drugs brings on diseased states. The impulse for alcohol and other narcotic drugs is always a symptom of some form of brain palsy. There are two classes of these cases in which this fact seems very clear. The first class are those with a history of some distinct traumatism—noticeably, sunstroke, blows on the head, profound wasting illness and severe injury of any kind.

Recovery follows, but with it appear changes of temper, character and emotions, then comes the drink impulse or the use of some form of opium. These drugs cover up other changes and are interpreted to be the cause of all subsequent degeneration and disease.

Many of these cases die of pneumonia or some other acute disease, others go on to insanity and become inmates of asylums, while the majority remain as common drunkards or inebriates slowly growing worse year after year. They are treated as low, voluntary inebriates, despised, persecuted and punished, and die the centers of wretchedness and misery, and frequently leave defective families that are always burdens to the world.

The *second class* of inebriates or drug takers have a distinct history of psychical traumatism. A man previously temperate and well, will have a history of profound mental shock, such as sud-

den overwhelming grief at the loss of wife, or children, or property, or the failure to realize some absorbing ambition, or some calamity that will distress him acutely. His entire character and disposition will change, and the drink impulse will appear suddenly, without any cause, and continue persistently.

Several instances have been noted in which the effect of a railroad accident, where no external injury was produced, was the beginning of the drink impulse. The shock of sudden fear seemed to so paralyze the brain as to demand alcohol or opium ever after. In these cases, alcohol may be taken at first as a medicine and in moderation, but the degeneration which calls for it is apparent when efforts are made to discontinue its use. Another class of cases show these symptoms equally marked; thus persons who occupy centers of great care and business or professional responsibility; persons who are most active in business in the prime of life, previously temperate, who suddenly begin to take spirits and rapidly become excessive drinkers, and defenders of its value as a medicine. Such cases are soon incapacitated and die. The drink symptom is always treated as a moral condition in these cases.

In the first class of physical traumatism some form of brain degeneration is apparent in this morbid impulse for alcohol and opium. The beginning and progress of the case confirms this.

In the second class of psychical traumatism, a brain palsy and sudden perversion of brain function and activity takes place, and the demand for alcohol and opium is the expression of this state.

In the third class, the use of spirits is a symptom of exhaustion and general brain failure.

All these forms of palsy and degeneration are rapidly intensified by the chemical action of the spirit or drug used.

The pathological condition which calls for relief by these drugs has a uniform order of events, beginning at a certain point and passing down, marked by a regular succession of symptoms, reaching a certain termination that rarely varies.

The drink craze is a symptom which should never be misinterpreted or overlooked. Any one who persists in using alcohol or opium to excess is suffering from some brain degeneration and disease, which requires medical study and care.

The use of alcohol or other drugs is, in a certain number of cases, a marked symptom of insanity. This fact has been noted for many years, and generally occurs in neurotics who, after some great strain or mental perturbation, become excessive users of spirits, and continuously or at intervals, stupify themselves with such drugs. When arrested and deprived of spirits in jails, acute mania or melancholy follows; then it appears that the spirit and drug craze were only

symptoms of insanity concealed and masked by the spirits.

The facts in this direction are numerous and startling, and unknown except to the few students who are at work in this field.

Scientific study has established this fact, viz.: that the "drink craze" (meaning the impulsive, unreasoning desire for spirits or narcotics) is a symptom of disease. Whether this is so in all cases at the beginning is not yet established; yet nothing can be more certain than this, that the use of spirits will cause disease and diseased conditions in all cases.

Another fact is becoming more prominent, that the number of inebriates of all forms is increasing; and with them the army of neurotics and defectives is likewise rapidly growing larger.

The problems of causation, prevention and cure are still involved in the realms of obscurity and quackery. Great parties and numerous societies are attempting its solution from the moral side alone.

As a scientific problem, it is practically unknown, and yet, no question of modern times is so eminently one of causes and conditions that are tangible and within the range of science to understand.

The neurologist must point out the road and stimulate the family physician to study these early psychical symptoms, which, like signal flags of distress, are becoming more apparent.

Scientifically the abnormality of an increasing army of neurotics and suicidal drug takers, who receive no care or medical attention until they are chronic, is a reflection on modern medicine.

Over five million of laymen in this country are agitating the question of means and remedies to check this disease. Of the sixty thousand physicians, less than a hundred have given any special attention to the cure and prevention of this wide reaching malady.

The specialists can study these cases in asylums, but the family physician must be the scientific student to point out the early causes and remedies. The drink problem can never be solved except from physiological and psychological study. This must begin with heredity, growth, nutrition, culture, surroundings and all the phenomena of life.

The early psychical symptoms must be studied also, the traumatisms, the beginnings of pathological changes that manifest themselves in the drink impulse.

This is the path along which science must seek the solution of this problem. The temperance agitator and reformer must give way to the physician. The roar and conflict of parties and societies will die away, and only the voice of science will be heard. Then the armies of inebriates, criminals, and insane will be halted, disbanded and forced back to health and rational

living. The inebriates will be protected and housed. The saloon will disappear, and alcohol will be unknown. This will be a reality when medical men take up this study from a purely scientific point of view.

In discussion Dr. Kiernan said:

He thought that Dr. Crothers did not fully appreciate the legal difficulties in caring for the inebriate. It is only when he has reached criminality that the law becomes efficient in restraining his morbid appetite. Additional difficulty was added to these cases by the confused rulings of courts regarding tests of criminal responsibility. There were, however, signs of advancement and a disposition to yield time honored but erroneous precedents. Inebriates should have the same legal status as lunatics.

THE NEUROSES FROM A DEMOGRAPHIC POINT OF VIEW.

Abstract of a Paper Read in the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY IRVING C. ROSSE, M.D.,
OF WASHINGTON, D. C.

The title of this paper may seem rather an ambitious one, since the study of vital and social statistics, and their application to the comparative study of races and nations, is almost too new to furnish many principles that may serve as bases of induction. However, I purpose to state in a fragmentary way a few notes and observations bearing on the subject.

More than usual experience as a traveller has brought me in contact with various races of men under different mesological conditions. Experience and observation in this line show that, in spite of physical and moral varieties, there exists practically, for the physician, but one people, since there are no wide differences, biologically or medically speaking, in the human species; and the infirmities of men, notwithstanding their physical inequalities and the extensive range of the nosological table, are much the same the world over, no matter whether they be classified among the white, the yellow, or the black races.

I confine myself advisedly to the simple classification of white, yellow and black, as it seems to be the best for descriptive anthropological purposes, and is, moreover, that adopted by Aristotle, Cuvier, and by a recent contemporary authority, Dr. Latham.

In the consideration of ethnological subjects there seems to be an inability, on the part of some people, to rid the mind of such abstractions as geographical lines and political distinctions, though it is well known that they will not keep away disease or noxious products. Indeed, the prejudice is carried so far that one might infer

the notion that being born in a stable makes one a horse. We should not lose sight of the fact that the offspring of an English man and woman in Africa will partake of the ethnological characteristics of the Anglo Saxon race for all time to come, so far as we know, and that the descendants of a black African man and woman in America will perpetuate the negro type with marked persistency. The latter fact is so well established that in studying cases of the crossing of the colored races, families have been observed in which, at the end of several generations, there were a series of children having much more than their father and mother the signs of an African mixture, going back at least to a fifth anterior generation. A woman whose father was a quadroon and whose mother showed traces of African blood, having married an Englishman of pure race, had nineteen children, all of whom showed unequivocal traces of this sixteenth of African blood (*Bulletin de la Soc. d'Anthropologie*, 1865, p. 288). Among the motley population of the West Indies, it is noticeable that the African negro, transplanted to a sky but a little different from his own, has scarcely undergone any physical or moral modification; in fact, he flourishes in the Antilles like the green bay tree, nature there being so much in his favor that after successive generations of mulattoes, the children revert to the negro type. Of course I do not pretend to deny the influence of meteorological conditions. Food and drink, and social and political surroundings; the conception of the remotest past and a forecast of the remotest future circumstances; everything in space, from a man's shirt to the farthest nebulae and deepest stratum of earth that he can infer, are but parts of the tremendous whole that acts upon man, or that he can act upon.

In the climate of the West Indies, for instance, which Darwin speaks of as a great wild, untidy, luxuriant hothouse, the combined effect of humidity with extreme heat softens, relaxes and impairs the fibres in men and animals, renders them lazy, inert, phlegmatic, and reduces them promptly to a state of complete atony. In these islands of indolence, even mosquitoes are lazy, and appear supremely indifferent when compared with the ones that I have seen inside the Arctic circle in Northern Alaska. Fish are not game. It is related with some show of authenticity, as evidence of climatic result, that the tarpon has allowed itself to be caught by fishermen who dived to the bottom and placed a hook in its mouth. Mice are also wanting in the alacrity that characterizes the northern species. Imported quadrupeds weaken and degenerate rapidly. The hog alone flourishes. Frenchmen do not acclimate and flourish in the Caribbean climate as they do, for instance, in Canada, under the same isotherm as Denmark, and Dr. Rochoux declares

that families who are not from time to time recruited become extinguished in the third and fourth generation.

It is true that atmospheric vicissitudes have much to do with the sicknesses of all latitudes, and may impart a different shade of color to a malady, that is produced by a sort of anatomical determinism. Meteorological influences of the climate modify the telluric conditions, alimentation, habits, etc., yet as regards climate, observation and experience seem to be our only guides. Up to the present time, climatology has given us many figures with but few results, and topography teaches nothing upon the salubrity of a country. It does not explain why cholera is in India, plague in Egypt, and yellow fever on the shores of the Gulf of Mexico. Nor does it tell why malarial fevers spare New Caledonia, in spite of the existence of numerous marshes, and why they ravage Madagascar in spite of its grand chain of mountains.

We, of course, do not look for sunstroke and malarial fevers among Eskimo, nor for frost bites and snow blindness among the natives of tropical Africa, yet I have found locomotor ataxia equally in Hayti and New York, and have seen the prevailing geophagism of the Antilles and South America among negroes of the Southern States.

This neurosis of the function of digestion is not the exclusive infirmity of degraded and primitive negro tribes. Pathological geophagy is found among the yellow races in Java, China and Siberia. It has been observed in the white race in some of the provinces of Spain, and among the poorer classes of whites inhabiting the pine barrens and thinly settled portions of several Southern States.

Gastric depravity is not confined to human beings. Collective investigation on this subject enables me to mention numerous instances.

I have known a sow to eat her whole litter of pigs, and I have seen coprophagy in one of the elephants confined in the London Zoological Garden. On observing the habits of the fur seal during four visits to the Prybolof Islands, I have learned that these animals are in the habit of swallowing stones. The lithoborous habits were confirmed by finding in many stomachs stones weighing $\frac{1}{2}$ lb. apiece. One paunch contained in the aggregate over 5 lbs. of large pebbles, and in the stomach of one sea lion there were found more than 10 lbs. of stones, some of them of great size.

If such facts as the foregoing convince the biologist of the identity of pathological phenomena occurring in the animal series with those observed in man, it is more striking from an anthropopathological point of view that there is stronger relation among diseases of men of all races, in all climates. Nervous diseases form no exception to this principle; for in a general way it is

true that all species suffer nearly in the same manner when exposed to the action of the same morbid causes.

In a retrospective way it is quite possible for a neurologist to study at the present time some of the convulsive manifestations of the Middle Ages; and if we have the snake worship, magical associations and nocturnal mysteries of voodooism in Africa and Hayti, is not our own country preëminently the land of spiritualists, mesmerism, soothsaying, and mystical congregations?

Much of my practice having been among Jews, I have had occasion to notice the calm, sober, and sedentary manners of that cosmopolitan race, in whom the prolonged influence of climate has certainly caused no material transformation of type. The world over, they preserve the Semitic stamp, and observe the excellent hygienic code that secures them such pathological immunity that it is said they are less often struck by lightning than other people. On the other hand, the phenomena of nervous and mental disease are more frequent in them than in other races.

We find familiar examples of strange nervous manifestations in such circumstances as a dance among the Sioux Indians, or a revival among the Anglo-Saxons at a camp-meeting. At both many of the participants will sing, laugh, weep, foam at the mouth, and fall exhausted in a faint or swoon.

Analogous conditions of nerve disturbance may be found equally among the black inhabitants of equatorial latitudes and the Hyperborean Mongoligæ who live under the midnight sun. Besides gross anatomical differences in the negro and a difference of personal essence, so to speak, we find an obtusion of peripheral sensibility, said to be owing to flattening of the tactile corpuscle. There is a want of fineness in the reflexes, lessened sensibility to alcohol, small intensity of nerve action, and, according to some observers, difference in the electrical state. I have noted similar things among the Eskimo of Bering Strait, the Tchutchkis of Arctic Siberia, and among the Innuir population generally. The nervous derangements of the Northern tribes, who, by the way, believe in and practice Shamanism, go to show that nervous diseases are not, as many people believe, confined to civilization. Among these people I have seen insomnia, epilepsy, chorea, cerebral hæmorrhage, paraplegia and hemiplegia, and suicidal mania.

A nervous affection known in the State of Maine as the jumping disease, has its analogue in the Siberian *emeryaki*, so prevalent in the vicinity of Jakutsk. I may remark incidentally that, in the original account of this affection given to the public, the word was incorrectly spelled. Dr. Bunge, of St. Petersburg, writes me that it should be written *emeryaki* in order to

approximate its Russian pronunciation. There is, besides, *emeryak*, the male patient; *emeryaki*, *emyraka*, the female patient; and finally a verb, *emeryatschitz*, to be affected with this disease. My friend, Lieut. Schutze, of the Navy, who has seen much of this disease, thinks it is owing to excessive consumption of tea and tobacco, and psychic depression of isolated communities and long polar nights.

The ancient habit of tattooing is still common among school boys, sailors, soldiers, criminals, and prostitutes living in so-called civilized communities. The practice, generally confined to a low grade of development and originating in perversion of the sexual instinct, is found pretty much over the world, notably in the Polynesian Islands and some parts of Japan, and I have been struck with the similarity of design on the chins of women when visiting two places so far apart as Morocco and Saint Lawrence Island. To anticipate criticism for mentioning what may seem a very trivial subject, I would say that tattooing is significant from a medico-legal point of view, no less a person than the Lord Chief Justice of England, having characterized it as a matter of vital importance.

As regards perversions of the sexual instinct and outrages on morals, our common humanity seems to have much the same aptitudes and instincts, regardless of the points of the compass.

Even a superficial observance of the sexual morals of the Eskimo causes one to smile at Lord Kame's "Frigidity of the North Americans," and at the fallacy of Herder, who says: "The blood of man near the pole circulates but slowly, the heart beats but languidly; consequently the married live chastely, the women almost requiring compulsion to take upon them the troubles of married life," etc. Nearly the same idea, expressed by Montesquien and repeated by Byron in "Happy the Nations of the Moral North," are statements so at variance with my experience, that this fact must alone excuse a reference to the subject. So far are they from applying to the people in question that it is only necessary to mention, without going into details, that the women are freely offered to strangers by way of hospitality, showing a decided preference for white men, whom they think beget better off spring than their own men. In this regard one is soon convinced that salacious and prurient tastes are not the exclusive privilege of people living outside of the Arctic circle; and observation favors the belief in the existence of pederasty among Eskimo, if one may be allowed to judge from circumstances not necessary to particularize, and from a word in their language signifying the act.

Coming nearer to home, we find that paranoia and general paresis are more common in the white race as they come under the civilizing in-

fluences of town life, the bad features of which are increased consumption of tea, alcohol and tobacco, exposure to venereal disease, and the unequal distribution of wealth. The same causes seem to have produced an anatomical determinism in the black race, among whom suicide and insanity were rare before the civil war, which goes to show that such affections are modified by mesological causes rather than by race.

I trust that the foregoing experiences, incomplete as they are, may call the attention of others to the study of pathological anthropology in its bearing upon nervous diseases; and if any observation of mine shall prove genetic enough to broaden the enthusiasm of the medical man, and enable him to show less hesitancy in the treatment of disease, then I shall not regret having claimed your attention.

In discussion of Dr. Rosse's paper, Dr. Osler referred to the remarkable fact that chorea was rare in the Indian and negro, also that locomotor ataxia was rare in the colored race, while syphilis was common. On the contrary, hysteria was a frequent disease among negroes.

Dr. Hughes said that Dr. Beard had made the observation that nervous diseases were relatively less frequent in the South than in the North.

Dr. Kiernan recalled that Dr. Spitzka, Dr. Bannister and himself had made a study of ethnological psychiatry. Paretic dementia, for example, was present in the negroes of New York and Chicago, but absent from those in the South. The reason for this was found in that in the cities named they were exposed to the same conditions that produced the disease in the white race.

Dr. Rosse, in closing, said that he had recently seen a case of locomotor ataxia in a full-blooded negro.

STATUS EPILEPTICUS.

Read in the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY G. R. TROWBRIDGE, A. M., M.D., AND C. B. MAYBERRY, A. M., M.D.,

Fellows of the American Academy of Medicine; Assistant Physicians State Hospital for the Insane, Danville, Pa.; Members of the American Medical Association, and Pennsylvania Medical Society.

It should be a source of regret that a prominent writer and authority in medicine, in the description of epilepsy, in his work on practical medicine, makes this statement: "As regards the immediate danger from the paroxysms, the prognosis is always favorable;"¹ and, moreover, he makes but bare mention of the condition status epilepticus, when in reality it is the most serious phase epilepsy assumes. It is for the very reason that but comparatively little consideration has been given to this condition by the

¹ Flint. Principles and Practice of Medicine.

profession, excepting the medical men connected with institutions for the insane, that it has been chosen the subject of a paper, with the hope that, without being obtrusive, a somewhat systematic description and a few suggestions in regard to the treatment of such cases may be given, which may be of some interest and value.

The alarming mortality among epileptics, shown by the reports of our asylums and hospitals for the insane, and due in a great measure to status epilepticus, makes constant demands for new suggestions and ideas in the treatment of these cases; and when, moreover, it is taken into consideration that every individual, whether in an insane asylum or not, who has fallen prey to the as yet unexplained disease, idiopathic epilepsy, either in a mild or severe form, may at any time be attacked with this almost surely fatal phase of the disease, it would seem that any point, either in clinical history, pathology or treatment, must be of interest to the profession, and certainly to the neurologist and alienist.

This paper has been prepared in the hope that it may possibly advance some new ideas, and at least be a reminder of this extremely serious phase of epilepsy.

As to the cause or causes productive of idiopathic epilepsy, we must, as yet, say we do not know, and consequently the same statement must be made in regard to status epilepticus; so the treatment of these cases will of necessity be dependent upon theory and symptoms.

Whether or not epilepsy is an entity and has but one cause in its production, or is a disease resulting from a number of factors, it is well known that it varies in intensity from a form which but slightly interrupts the daily routine of life to one which utterly destroys the individual physically, mentally, morally and socially, and no matter how mildly the neurosis may exhibit itself in a special case, the individual has the taint of lesion, which at any time may be productive of violent convulsions, and in a few hours carry its victim into eternity.

It is as if one were standing near a comparatively innocent and harmless stream; but the bursting of a dam sets in motion the pent-up flood, and in an instant he is swept into oblivion.

If we accept the theory of J. Hughlings Jackson regarding the cause of epilepsy, viz., an over-discharge of nerve force, or energy, from the brain cortex, we might define status epilepticus as a continuous, rapid and violent discharge of this nerve force, followed by a condition of extreme stupor verging upon coma, or, in place of the stupor, a period of maniacal excitement, though this latter is extremely rare.

Status epilepticus can scarcely be considered a special form of epilepsy, nor is it all correct to make it a distinct disease, but, on the contrary, it should be regarded as a climax of epilepsy.

A condition resembling status epilepticus may result in epileptics in whom the disease is caused by gross lesions, as tumors, cysts, etc., and to a considerable extent it is analogous to the epileptiform seizures, and consequent condition of parietic dementia; but it is not the purpose of this paper to treat of such cases.

In order to preserve as far as possible a systematic order in the consideration of the subject, the following headings are given:

1. The clinical history.
2. Resumé of cases treated.
3. Notes of autopsies.
4. Prognosis.
5. Treatment.

The clinical history of status epilepticus, "état de mal," or "les séries," of the French, or, as Charcot calls it, "the epileptic acme," from observations made by the writers upon the cases to be cited hereafter, is as follows:

A rapid succession of convulsions, usually of "grand mal" type, with intermissions varying from a few seconds to a few minutes, and often following one another so closely that they resemble one continuous convulsion, the patient being in a stuporous or even comatose condition in the intervals.

The pulse and breathing are greatly accelerated, the former being weak and irregular; there is deep congestion of the face and neck and intense throbbing of the carotids.

The temperature rises rapidly, until it has reached 104°-107° F., and there is often a difference in the temperature of the two sides, the greatest heat being on the side which is most convulsed.

As the convulsions increase in frequency and violence, there is a corresponding rise in the temperature and a deepening stupor or coma in the intervals. The conjunctivæ are insensitive; the pupils are widely and (as a rule) evenly dilated, though occasionally there is a difference in size, and are not affected by light; patient is bathed in a cold sweat, though the skin feels intensely hot; sordes appear on the gums and teeth, and the bladder and bowels are involuntarily evacuated. This condition may last from one to several hours; but, as a rule, the convulsive stage is of comparatively short duration, though occasionally it is prolonged.²

Death may occur in this stage from exhaustion, or the convulsions may cease and the patient pass into the second or stuporous stage.

This stage is characterized by an intense stupor, total abolition of sensation and motion, exceedingly depressed heart's action, and a consequent dyspnoic condition. The temperature re-

² One patient in the West Riding Asylum had 1,849 convulsions, covering a period of fifteen days. Delasuiave reports a case where the first stage lasted a month, the patient having 2,500 fits. A patient in the Northern Michigan Asylum had 3,000 in three weeks.

mains above normal, though not as high as in the convulsive stage.

There is paralysis of the muscles of deglutition, very often irritability of the stomach, and sometimes profuse diarrhœa; bed sores appear; the tongue is dry and coated; increasing sordes on the teeth and gums, and, in short, everything points to a rapid dissolution. The second stage lasts from one to several days.

Charcot³ makes two classes of status epilepticus, viz., "the minor acme ('les petites séries'), constituted by from two to six fits, and the major acme ('les grandes séries'), in which from twenty to thirty fits have been reckoned in the twenty-four hours." It would hardly seem that this division is necessary, for the very reason that it is an extremely rare occurrence for from two to six fits to produce the stuporous stage of the status proper. Evidently Charcot regards the convulsive stage as constituting status epilepticus without including the comatose stage. Hence his two classes.

Rosenthal⁴ gives the following description: "Another severe form of epilepsy is described under the name of status epilepticus. It presents the following characteristics: Rapid succession of attacks, presenting slight remissions and without return to consciousness (convulsive stage); a comatose condition secondary to these attacks, with abolition of reflex power, except during short periods of temporary increase (meningeal stage); more or less complete and permanent hemiplegia; acceleration of the pulse and respiration; and especially a marked elevation in temperature (40°-43° C.), which persists even in the intervals of the paroxysms, and may increase after their disappearance. The duration of these attacks may vary from three to nine days; more than one half the cases terminate in death."

Putzel⁵ gives the clinical history in the following words: "The prodromata do not differ in any respect from those which are usually experienced by the patient prior to the ordinary attack of convulsions; but the fits, instead of ceasing, follow one another rapidly, and before the epileptic coma has entirely disappeared, another convulsion makes its appearance. The intervals between the fits become shorter and shorter, until they run into one another and finally the patient appears to be in one long continued convulsion.

"The pulse is regular, but usually small, the respirations become frequent and labored. The temperature begins to rise from the very beginning, and may rapidly reach a height of 104°, 105° or 107° F., and upward. The skin is hot and scorching, the face is covered with an abundant, viscid sweat. Marked nystagmus is present,

and the face and neck may be drawn to one side. The pupils are dilated, either equally or unequally, and do not react normally to light.

"After the convulsions have lasted some time, hemiplegia develops in a large number of cases, the face and limbs being affected as in ordinary hemiplegia. . . . The sensorial and intellectual functions are totally abolished, and the patient lies in a profound stupor, which often deepens into coma."

Secondary or Meningitic Stage.—"At the close of the first stage the convulsions become more infrequent, and finally cease, but another series of symptoms develop. The intelligence is more or less affected, and the patient is in a condition of hebetude or coma." The author goes on to say that in this stage the coma may be replaced by maniacal excitement, general disturbance of nutrition, emaciation, bed-sores, and a gradual dissolution or an extremely slow recovery.

Bevan Lewis⁶ describes it as follows: "If the attacks succeed each other rapidly and consciousness is not restored between the convulsive seizures, if fit succeed fit at intervals of a few moments only, the patient remaining comatose, we have developed what is termed the status epilepticus, a condition of most serious import.

"The pulse and breathing become quickened; . . . the temperature rises to 105° or 107° F., with deepening coma or stupor. . . . As the fatal termination approaches, the convulsions become more frequent, a few seconds only intervening between each discharge, so at times they appear almost continuous, a fresh discharge being only recognized as a slight increase in the intensity of the convulsions.

"When this period arrives, however, the epileptic discharge becomes progressively feeble, and the fit may be characterized by a slight turning of the head and eyes to one side, with slight clonic movements of the limbs or merely convulsive twitchings of the mouth, with conjugate deviation. The conjunctivæ are, of course, quite insensitive, the pupils being widely dilated and fixed to the strongest glare of light, while the face and body are bedewed with a cold sweat. Often the temperature exhibits unilateral deviations, being highest by a degree or more on the side first (or most) convulsed. If the patient recover, the fall of temperature is most rapid on this side until a balance is established, and subsequently an equal and continuous decline of temperature proceeds on both sides. . . . The mortality from status epilepticus is said to be due to (a) collapse and (b) meningitis."

Bourneville⁷ in his treatise characterizes status epilepticus: 1. By the frequent repetitions of the convulsions, which may even become almost

continuous with one another; 2, by a variable degree of collapse, which may deepen into a most profound coma, unattended by any return to consciousness; 3, by a more or less complete hemiplegia, developing after a variable duration of the symptoms; 4, by increase in frequency of pulse and respiration; 5, by considerable elevation of temperature, which persists in the brief interval between the convulsions. He, with others, divides it into two periods—a convulsive and meningitic.

Calmeil, Trousseau, Delasuiave, Gowers, Webber and Blandford give more or less on the subject; but as their statements are covered by the authors already quoted, it is useless to give them here.

Twenty cases of status epilepticus have come under the observation of the writers; but only twelve are cited, as the remaining eight would only be repetitions of the others.

Case 1.—Male, aged 25; congenital imbecile; family history shows marked neurotic taint; had scarlet fever when 15 years of age, and soon after recovery epilepsy appeared; has had an average of ten fits a month since development of the neurosis; physical condition much impaired. During November, 1888, had three fits; December, eleven, and January, twenty-four.

All of this time he was taking a mixed tonic and bromide treatment. On February 24, at 2 P.M., after an interval of several days without fits, he had a severe convulsion, followed by others in rapid succession, averaging one every two minutes for the first hour. At three o'clock his temperature was 102° F., respiration 30, pulse 106, skin hot and covered with perspiration, pupils dilated equally and not reacting to light, face much congested; unconscious, though not having a convulsion at that time. Ether was given and carried to surgical anæsthesia, with a cessation of the convulsions. Given chloral hydrate, grs. xxx, by rectum. Slept well until 9 P.M., but on awakening he immediately went into a series of convulsions, having thirteen in twenty minutes. At 9:30 P.M., temperature was 104° F., respiration 35, pulse 130. Ether was again administered, and morphine sulph., grain $\frac{1}{4}$, hypodermically. February 25: Slept well during the night. This morning he lies in a stupid condition; temperature 105.6° F.; respiration 41, pulse 129, cold sweat over entire body, pupils dilated and insensible to light. Given nourishment and stimulants by stomach-tube. Remained in this condition until death, at 5 P.M. Duration of attack, fifty-seven hours; number of convulsions, forty-three.

Case 2.—Male, aged 28; congenital imbecile; had scarlet fever when ten years old, and immediately after developed epilepsy; no known heredity. During February, March and April, 1889, he had one fit while under tonic treatment. On May 2, between 1 and 5 A.M., he had one hundred

and six convulsions; at 5 A.M., temperature was 104.5° F., respiration 32, pulse 130. The fits followed each other with very short intervals, the patient being unconscious. Chloroform was administered, and continued for a half hour; ol. tigllii, gtts. iii, followed by profuse evacuations. In this case the convulsions were general, but stronger on the right side; right hemiplegia followed the attack. Patient sank into a stupid condition which lasted five days. During this time the temperature and pulse were constantly above normal, the gradual return to consciousness being preceded by an even fall of temperature. Sordes collected on the teeth; tongue brown and dry. The reflex action of the eyes was lost, and death seemed imminent. Stimulants and nourishment were given constantly by the nasal tube. On the fifth day he recovered consciousness; the temperature slowly fell to normal. Rapid improvement followed, and in ten days he was able to be about the ward. The total duration of the convulsive and comatose periods was about ten days; number of convulsions, one hundred and six.

Case 3.—Same patient as Case 2. On October 27, 1889, was found in the morning in a comatose condition, which, without doubt, resulted from his having passed through the convulsive stage of status epilepticus during the night. Temperature 105° F.; impossible to arouse him from the deep coma; pulse weak and intermittent. Stimulants and nourishment given per nasal tube. The physical exhaustion was so great that the man sank rapidly, and died eight hours after first being seen.

Case 4.—Male, aged 30; neurotic family; epileptic from childhood; no specific history; in good physical condition. Has had several attacks of status epilepticus, of which no record has been kept. These attacks were all marked by the large number of convulsions, their severity, the rapidity of their occurrence, and the short intervals between them. On February 21, at 3 P.M., the convulsions began while the patient was outdoors. When first seen he had had fifteen convulsions within a half hour and was in an extremely exhausted condition. Temperature 102° F., pulse small, body covered with cold perspiration. The convulsions were general and of uniform severity on the two sides. Conine hydrobrom., gr. $\frac{1}{100}$ was given hypodermically. One convulsion followed the injection, after which the patient sank into a quiet sleep, lasting six hours. On awakening his condition seemed much improved; temperature 99.8° F., pulse 106; conine, grs. $\frac{1}{100}$, with digitalin, gr. $\frac{1}{100}$, given hypodermically. Slept during the night without convulsions. Next morning he was much better, though very weak. Stimulants and nourishment. Two days after was about the ward as well as before the attack.

Case 5.—Same patient as Case 4. On April 15 had twenty convulsions, followed by great exhaustion. Given ether to anæsthesia, chloral, grs. xxx, by rectum. At intervals for twenty four hours he had convulsions of a more or less severe character, followed by stupor, from which he could not be aroused. Stimulants, nourishments, injections of ether, digitalin and atropiæ sulph. were given without effect. Patient gradually failed and died ten days after. The highest temperature in this case was 105.2 F., which occurred just before death. For some weeks before each of these attacks the patient had been taking bromide treatment.*

Case 6.—Male, aged 45; no known heredity; cause of epilepsy unknown; bodily in good health; weight 170 pounds; has very few epileptic convulsions, usually not more than six in a year; during the four months before the attack had three convulsions; several previous attacks of status epilepticus. This attack began May 4, 1889, at 7 A.M., and in one hour he had thirty-two convulsions, which were continuous, the intervals between the fits being marked only by a slight diminution in the severity of the convulsions. At 8 A.M., there were no signs of exhaustion; temperature 100° F., pulse 90. Given ether to anæsthesia and morph. sulph. gr. $\frac{1}{3}$, hypodermically. No diminution in convulsions except while under ether. At 9:30, chloral, grs. xxx, by rectum, after bowels had been moved by enema. At 11 ether was given and carried to surgical anæsthesia, without effect. At 12 coninæ hydrob., gr. $\frac{1}{100}$, hypodermically; a few minutes after he had a single fit, and this was followed by sleep. This same dose was repeated at 6 and 9 P.M. Slept all night. No convulsions in the morning, no excitement. An interesting feature of this attack is the absence of excitement, which has always before followed status epilepticus in this patient.

Case 7.—Admitted July 8, 1889. Male, aged 38; family history of insanity and epilepsy. On January 4, 1890, was attacked with status epilepticus, though since admission has only had five convulsions; fits followed each other so closely that attendants were unable to count them. When first seen, the convulsive stage had nearly ceased. Ether was administered, and morphine hypodermically. The convulsions were stopped entirely, but the man died in the second stage from exhaustion forty-eight hours after the commencement of the attack.

Case 8.—Male, aged 26; no known heredity; a deaf-mute; febrile disease in early childhood is the supposed cause of epilepsy; has had an average of five epileptic fits a month while under a mixed tonic and bromide treatment; physical

condition is usually good, but at present somewhat impaired from constant use of bromides. May 25 had a series of convulsions in the night, number unknown, but when first seen he was passing from one fit to another without any marked interval. Given hyoscine hydrobrom., gr. $\frac{1}{100}$, hypodermically, at 4 A.M. Slept until 7 A.M., and was then awakened by a convulsion, which was immediately followed by others; given amyl nitrite by inhalation, without effect; ether administered, and chloral, grs. xxx, per rectum, with but a temporary cessation of convulsions; 12 M., coninæ hydrobrom., grs. $\frac{1}{100}$, hypodermically, after which the fits ceased and sleep ensued. At this time his physical condition was bad; temperature 104° F., pulse 142, body covered with cold perspiration, face cyanotic, hands and feet cold. At 9 P.M. he was somewhat restless, although there had been no recurrence of the convulsions; slight muscular movements in different parts of the body. Given nourishment and whisky per nasal tube, an enema, digitalin and coninæ hydrobrom., $\bar{a}\bar{a}$, gr. $\frac{1}{100}$, and atropiæ sulph., gr. $\frac{1}{80}$, hypodermically. Slept during the night without a convulsion, and is less stupid this morning; takes nourishment and stimulants. From this time he improved gradually, and in five days was about the ward again.

Case 9.—Same patient as Case 8. For past two months has had no convulsions under a mixed tonic and bromide treatment. August 20, at 2:30 P.M., an attack began similar to the last; physical condition much better than at time of last attack. When first seen had had thirteen convulsions; temperature 100° F., pulse 110. Given coninæ hydrobrom., gr. $\frac{1}{100}$; slept until evening without convulsions and was in good physical condition; takes nourishment this morning, and was able to be about the ward on the following day.

Case 10.—Male, aged 46; family history shows a predisposition to nervous disease; duration of epilepsy unknown; has a history of syphilis twenty years ago, but there is no indication of cerebral disease or that his convulsions are not true epilepsy. At the time of his attack he had had no convulsions for several months. On December 16, 1890, had three fits in the afternoon, followed by seven in the evening without physical failure. At 9 P.M. given coninæ hydrobrom., gr. $\frac{1}{100}$; slept during the night without recurrence of the fits. At 8 A.M. convulsions again occurred the same in character as before. Given chloral, grs. xxx, and potass. bromide, grs. 60, by stomach, without effect, also morph. sulph., gr. $\frac{1}{3}$, and atropiæ sulph., gr. $\frac{1}{80}$, with the same negative effect; at 11 P.M., coninæ hydrobrom., gr. $\frac{1}{80}$, with an immediate cessation of the convulsions. Patient rapidly improved, and in two days was in his usual health.

Case 11.—Male, aged 45; family and previous

* Bromide of ammonia, bromide of sodium, $\bar{a}\bar{a}$ gr. xv., suspended in a tonic mixture, t. i. d., and a pill of oxide of zinc, extract of belladonna, $\bar{a}\bar{a}$. gr. $\frac{1}{4}$, at night.

history unknown; has had previous attacks of status epilepticus, all having two points in common, viz.: 1. The large number of fits and their rapid occurrence, and 2, a state of secondary consciousness following such attacks in which the patient was greatly excited and very brutal; violent to any one who came near him. Physical condition good; has had three fits in the last three months. On May 10, at 4 P.M., he had a severe convulsion, followed by others with intervals of about two minutes between them. At 4:20 he was etherized, after taking chloral hyd., grs. xxx, and potass. bromide, 5 i. On coming out of the anæsthetic, no convulsions occurred until 5:30 P.M. At 6 he was given coninæ hydrobrom., gr. $\frac{1}{10}$. Slept during the night without convulsions. No attack followed this, and the man rapidly returned to his usual condition. The highest temperature during this attack was 104° F., pulse 110.

Case 12.—Same patient as Case 11. Physical condition impaired; no convulsions for several weeks. September 30: had twenty-three fits between 11 A.M. and 12:30 P.M. Given coninæ hydrobrom., gr. $\frac{1}{10}$. Convulsions ceased. Slept until 7 P.M., when the convulsions again commenced; coninæ repeated with same good result. October 1, had several severe convulsions, followed by unconsciousness, stertorous breathing and right-sided hemiplegia. After being in this condition for about fifteen hours, death occurred. Temperature in this case ranged between 103° on the first day of the attack and 107° at time of death.

Such are the histories of twelve attacks of status epilepticus.

Of the twenty cases which have come under our care, four were examined post-mortem.

These examinations showed certain points common to all: 1. A lack of symmetry in the two hemispheres, which is so often found in epileptics; 2, an inequality in the weight of the two hemispheres, also quite common in epileptics; 3, more or less extensive decortication; 4, intense engorgement of the brain and its membranes—the sinuses were filled with blood, the vessels of both the dura and pia were distended, the brain on section showed the puncta vasculosa to a marked degree; 5, in all four cases, and especially marked in two, serous effusion into the ventricles and arachnoid space.

In one of the cases there was softening of the first and second temporo-sphenoidal convolutions on the right side. In another, which showed all the symptoms of apoplexy toward the end of the attack, a large hæmorrhage from the middle cerebral artery on the left side was found.

In a third case, in which death occurred instantly and during a convulsion, a small hæmorrhage was found in the medulla.

In none of these four cases was the cause of

the status epilepticus found, and in only two was there evidence of the immediate cause of death. The others, in all probability, died from the exhaustion consequent upon the convulsions.

The prognosis of status epilepticus is very unfavorable, the mortality being estimated at fifty per cent. The violence and frequency of the convulsions; the high temperature; the rapid, weak and irregular pulse; the consequent comatose condition, with its accompanying extreme depression, are all factors of such grave import that the outlook in most cases is very serious. Besides this, we must take into consideration the mechanical action brought into play, viz., the intense and powerful contractions of the muscles during a convulsion, which by exerting an irresistible pressure on the vessels, force the blood into the cerebral vessels, thus producing the great engorgement, with imminent liability to cerebral hæmorrhage.

Even though the individual passes safely through the status, hemiplegia often results, leaving him in a weak and helpless condition, and totally unable to withstand a second attack.

The three most probable modes of death are: 1, exhaustion; 2, from cerebral hæmorrhage; 3, from serous effusion.

Treatment.—In a condition like status epilepticus, where the life of the individual may be destroyed in a few hours, any measure which will abort the attack is of the greatest importance. Our treatment must be chiefly symptomatic, at least until more is known of the pathological condition than we know at present. There are two important indications for treatment which must be met in each case: 1. To bring the convulsive period to an end as quickly as possible, and 2, to sustain the life of the individual through the stupid or excited period which may follow the attack.

1. In order to meet the first indication for treatment, a large number of drugs have been tried, with a view of depressing the motor centres of the cerebrum or cord, or of paralyzing the efferent nerves, or all of these, and thus preventing a fatal termination, either by diminishing the number of convulsions, making them less severe, or preventing them altogether. Among the therapeutic measures suggested to fulfill this indication, we shall consider only those with which we have had personal experience in our own cases. These include the following: Ether, chloroform, chloral hydrate, bromide of potassium, nitrite of amyl, sulphate of morphine, sulphate of atropine, hydrobromate of hyoscine, salicylate of physostigmine, and hydrobromate of conine.

Ether and chloroform are given with the purpose of immediately stopping the convulsions by paralysis of the motor centres of the cerebrum and complete muscular relaxation.

However successful these may be in the convulsions of Jacksonian epilepsy, in our experience in cases of idiopathic status epilepticus they are but temporary measures, the convulsions ceasing only when the point of surgical anaesthesia has been reached, and coming on again before the patient has regained consciousness. They are of great use, however, in preventing the convulsions when exhaustion is imminent, while waiting for some other agent to act. Either may be used; but in a case where the heart and respiration are already in a weakened condition, ether would be the safer.

Chloral hydrate by the rectum has succeeded in some cases, but has more often failed. In giving this drug, it has been the custom to keep the patient under an anæsthetic during its absorption, giving grs. xxx, and repeating it in an hour if necessary. Although acting as a depressant of the spinal cord and brain, yet the amounts which can be given with safety are usually too small to produce the desired effect. We have not used it hypodermically, but it seems probable that used in this manner the results would be much better.

Bromide of potassium has been given in several cases in combination with chloral hydrate, but without any good results. If, as in several of our cases, status epilepticus follows a course of bromide treatment, very little could be expected from it, and indeed in any case, its action is so slow that but little could be hoped for from its use. In the few cases in which we have tried it, it has been given in doses of ʒi-ʒii .

Nitrite of amyl is highly recommended by some authors; but repeated trials have failed to establish its value. It has been given by inhalation, ʒ x , repeated at intervals. Although undoubtedly useful in preventing an impending convulsion of ordinary epilepsy, it has proved of but little value in the cases of status epilepticus in this hospital.

Sulphate of morphine has succeeded in one case in which gr. $\frac{1}{2}$ was given hypodermically during ether anæsthesia; but in several other cases in which it was used it failed to change the course of the attack in any appreciable way, although given in doses of gr. $\frac{1}{4}$ – $\frac{1}{2}$, hypodermically.

Sulphate of atropine, in any safe dose, acts strongly upon the cardiac and respiratory centres and upon the pneumogastric nerve, but very slightly upon the motor nerves of voluntary muscles. Carried further than this, it stimulates the cardiac sympathetic and paralyzes the pneumogastric, and in consequence there results a rapid heart failure. For this reason it is impossible to stop the convulsions without cardiac failure. Its immediate effect has been good by its stimulating action on the vagus and the resultant improvement in the character of the respiration and circulation. Although it has been

used with a view to stopping the convulsions, it is of more value in the second stage of neurosis.

Hydrobromate of hyosine, if given in sufficient amount hypodermically, produces almost immediate sleep, affects the motor tract of the spinal cord and cerebral cortex, and in a case in which its use is not contraindicated by weakness of the heart or respiration, its employment promises good results. In the cases in which it has been used, the convulsions have quickly ceased, the heart's action has been slightly depressed after a short time, the respirations have been more frequent and less full, and sleep has followed, lasting from two to eight hours, with a recurrence of the convulsions on awakening, and an improvement has occurred in the patient's condition. Although hyosine has failed to bring the attack to an end in any of these cases, yet the rest and freedom from convulsions for several hours, with the resulting improvement in the bodily condition, would indicate its use as a temporary measure. It has been given in doses of gr. $\frac{1}{8}$ – $\frac{1}{16}$, hypodermically, its success in acute mania when given by this method, and its almost complete failure when given by the stomach, suggesting a similar result in status epilepticus.

Salicylate of physostigmine, gr. $\frac{1}{64}$, was given in one case with a view of depressing the cord sufficiently to stop the convulsions, but without success.

Hydrobromate of conine was first used in a case in which most of the other measures in this list had failed, and its use was followed by an almost immediate cessation of the convulsions. Its action is from the periphery, extending toward the centre, the motor nerves being chiefly affected, the sensory nerves remaining almost unchanged. When a case in which it has been given is carefully watched, the following results are noticed: 1. Weakening of the convulsive movements, beginning at the lower extremities, and extending upward over the trunk and upper extremities, and last the head and face, with finally a complete cessation of the movements if a sufficient amount has been given; 2, slight dilation of the pupils and ptosis; 3, some impairment of general sensibility; 4, heart slow and full, respiration slow and labored; 5, combined with sulphate of morphia, sleep follows, lasting several hours; 6, if the convulsions are to return, as the influence of the drug is lost, fibrillary contractions, beginning above and passing downward—that is, in the opposite direction from what they ceased—and finally the general convulsions are reestablished. This drug has been given in small doses, gr. $\frac{1}{16}$ – $\frac{1}{32}$, hypodermically, and repeated as often as indicated, the administration being guided by the character of the respiration. It has usually been combined with sulphate of morphine to produce sleep, and sulphate of atropine to act as a stimulant to the

respiratory and circulatory organs, and also at times with digitalin and hyoscine. Only two of the cases in which it has been used have terminated unfavorably. In the first it stopped the convulsions; but they recurred, and cerebral hæmorrhage complicated the case. In the second case it was given, as were all the drugs mentioned, the only measures attended with any success being the administration of ether and chloroform, until there was complete muscular relaxation; and in this case the patient died suddenly, while in a fit, from hæmorrhage into the medulla. In several of the cases, conine and a small amount of morphine have been the only drugs used. Although it failed to control the convulsions in one case, yet it has been the most successful method of treatment tried, and its results encourage us to believe that it will succeed in the majority of cases of status epilepticus.

2. The exhaustion of the patient gives the second indication for treatment. In almost every case of status epilepticus, before the convulsions can be controlled there are evidences of physical failure; the pulse is rapid and weak, the respiration shallow and increased in rapidity, the temperature raised several degrees above normal, and a profuse perspiration covers the body, all of which call for immediate treatment in order to carry the patient through the dangerous period. The condition of the patient usually prevents the administration of food or medicine by the mouth, although if introduced into the stomach they will be retained. To fulfill this indication, we have introduced two methods: 1. The hypodermic use of such agents as atropine, digitalin, *spt. frumenti* and quinine sulph.; and 2, the introduction of milk, eggs and stimulants into the stomach by means of the nasal and stomach tubes, on account of the inability to swallow; artificial introduction of food into the stomach being especially called for in cases in which the stupid or excited periods are of several days' duration.

The conclusions drawn from this paper are as follows:

1. On account of its association with epilepsy, status epilepticus should not be considered a distinct disease, but merely a climax of the neurosis.
2. It consists of two stages: 1. A convulsive, and 2, a comatose, though the latter is sometimes replaced by a period of maniacal excitement.
3. That there is no demonstrable lesion causative of the status.
4. That the prognosis is unfavorable.
5. That the treatment is in a measure symptomatic, but considerable reliance can be placed upon the hypodermic use of the hydrobromates of hyoscine or conine combined with the sulphate of morphine.

FUNCTIONAL BRAIN DEGENERACY.

Read in the Section on Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY J. T. SEARCY, M.D.,
OF TUSCALOOSA, ALA.

It is interesting to notice how much we are given to the habit of grading and estimating others in society. We are continually engaged in this kind of work, and we consider the opinions we have of our acquaintances and associates as very valuable items of information. So intuitive and instinctive is this kind of work that we do it unconsciously, as it were; and as soon as we make an acquaintance, we find ourselves silently estimating and classifying him.

The two particulars in which we generally consider it very important to estimate others are, first, their intellectual ability; and secondly, their ethical sense. We call these "mental and moral qualities," and recognize that they are more or less distinct and separate.

In common with all other living beings, man lives in competitive life; and so fundamental and continuous, from the earliest existence of life in the world, has been the necessity of alertness and observation in order to survival and continuance, that man, in common with all other sentient beings, has acquired a constant sense of insecurity on account of rivalry. We are all born with an instinctive knowledge of this fact. It haunts us from our earliest consciousness, and it follows us all through life. By highly advanced and improved brain capacity, and by suppression of rival species, man has so widened the distance between himself and lower grades that, comparatively, he recognizes little danger from that direction. His principal rival is his fellow-man.

It is this instinctive sense of insecurity on account of rivalry, that begets the instinctive habit in us of grading and estimating our fellows.

We wish to know at once how formidable a competitor our new acquaintance will prove, hence we promptly grade him in intellectual ability; and we wish to know whether he will conduct his competitions or associations with us in accordance with established and advanced rules of decorum and propriety—hence, with equal promptness, we grade him in ethical sense.

By the long progress of practice, we have become exceedingly expert in this kind of work. Some boast they can frame an opinion from as slender a foundation as expression of face, the cut of the eye, the step on the pavement, the handwriting, the tone of voice, or style of dress. Of course such expressions are exaggerations, still they show how adept we have become, and how much we value such information.

As we estimate men in these particulars, we grade them into types, from the lowest savage, who is both very ignorant and very immoral, to

the highest civilized, who is both highly intelligent and highly moral. Between these extremes there is every conceivable grade, variety and type.

In the gradual rise of man from the state of savagery to that of civilization, his steady progress is occasioned by and marked by gradual improvement in both these particulars. There is a steady improvement in him of intelligence, and a steady improvement in him of ethical sense.

We readily recognize that the person who succeeds and excels is the intelligent one. He surpasses others in the competitions of active society. Intelligence is very plainly a double qualification. I would divide it into two parts: the inherent brain-ability of the person to think—intelligence, and the acquisitions he has made by thinking—knowledge. Ability to think is by far the most important, and whatever tends to improve or lower this qualification of the person tends to raise or lower his amount of knowledge, and his chances for success in the world. The person with a high order of brain capacity can and does acquire knowledge as the occasion requires. By intelligence, therefore, I mean capacity to think and knowledge combined.

In the slow and gradual advance of man, through generations, from a savage condition to a highly civilized one, it is the gradually increasing necessities occasioned by the competitions of a more and more complex society, that force him, in order to avoid suppression and elimination, to steadily improve his brain ability to think. The elimination of those least fit in brain capacity, and the survival of the more fit, is the natural method of gradual improvement in humanity. The original source of improved capacity and of accumulated knowledge, that is, of intelligence in the world, is therefore competitive life, and it is very easy to trace back all varieties of intellectual ability to the gradually acquired brain capacity that has been the result of the struggles for existence and for ascendancy, carried into the more and more complex and refined methods and habits of advanced society.

As society advances, we notice that not only is there an advance in intellectual qualifications—in ability to think—but almost *pari passu* with this line of capacity, there also is acquired another habit of thought, namely, an ethical sense.

As soon as human society begins to grow complex, then arises the public necessity that the competitions of its membership shall be regulated. Families, communities and races soon become themselves aggregated into wholes, individualized, because they become competitors with other families, communities and races, and public good demands that the internal rivalries of their members shall be so harmonized and so adjusted to each other as to subserve general welfare. Public safety demands ethical observances, and a

large proportion of the efforts and powers of society are spent in the inculcation of rules of conduct that relate to public good; in this the rules, laws and government of society, with the moral sentiment and public opinion that back them, as men become intelligent, become of a higher and higher grade, until those that harmonize and adjust the associations and competitions of the most advanced society are reached.

For these reasons the individual member of advancing society, besides becoming by competitive practice more and more capable intellectually, at the same time, becomes more and more habituated in the performance of ethical observances. The habit of adjusting conduct ethically, that is, according to established rules of society and the rights and wishes of others, becomes more and more fixed as a trait of character.

My object in this sort of observation is to draw attention to the fact that the tests by which we grade and classify our fellows—their intellectual and ethical abilities—are the results of the gradual practice and exercise to which men have been submitted through generations on generations of advancing, developing existence.

A most advanced man, therefore, is he who has such intellectual ability to think, that he can so understand the complexities of advanced society as to be able to formulate and promulgate the highest and best rules of conduct, and has such an ethical habit inherent in him that he holds true by an educated conscience in the observance of them.

The highest type of man, in short, is he who has the highest intellectual sense, coupled with the highest ethical sense.

Brain strength, like muscle strength, is the result of previous practice and exercise. All-round ability is the result of all-round work, and specialized accomplishments are the results of special kinds of practice. In brain-work, as in muscle-work, the exercise, in order to be improving, must reach the degree of being effort. Unless there is a constant sense of effort in muscle-work, muscle strength does not improve; the same is the case in brain-work. Brain work is therefore necessary in order to continue brain capacity; and in order to raise the level of capacity, increased effort is necessary. Previous activity alone produces capacity; continued activity alone continues capacity; and increased activity alone increases capacity.

The previous activity that produces capacity is either ancestral or individual. In biological descent the individual only represents one link in a chain of activity. The person gets his ability from the line of his ancestry—receives it at a certain level, and maintains or raises it solely by his own activity. Heredity means no more than the continuance in the line of the habits of action established in the ancestor. Of the two

elements of intelligence which I have mentioned, viz.: capacity to think and knowledge, capacity is inherited, knowledge is not. Knowledge has to be acquired, but by far the greater part and the best part of the capacity is inherited from ancestry, and is the result of previous ancestral brain exercise.

Brain abilities are not constant qualities; they vary in the life of the person and in the line of descent according to habits of thought. Practice alone produces; practice alone continues; and increased practice alone increases brain abilities.

According to these rules, our high-grade intellectual person is the result of previous ancestral and individual intellectual practice, and is, at the same time, ethical to a high degree, because of high-grade ancestral and individual ethical practice. The highest type of man, the one highly intelligent and highly ethical, is solely the result of the practice of both these kinds of brain work, and can occur only in that sort of advanced society which has been active and industrious, so as to have necessitated brain activity on the part of its members, and in that sort of society where the study and observance of high ethical rules are a constant practice.

No community, no matter how civilized, is uniform in its membership; we can find low types of men everywhere. In the most advanced society its membership will grade from the highest type—highly intelligent and highly ethical, to the lowest—very ignorant and very immoral. Brain abilities are not constant qualities. There is no constant level of capacity; it rises and falls according as the brain is practiced or not practiced.

While, therefore, we may state that activity improves capacity, we can with equal accuracy assert that inactivity lowers capacity. Much—probably most—of the impaired or lowered brain capacity in society comes from brain idleness. Functional capacity begins at once to lapse if functional brain activity is abated. We witness this on all sides: whatever conditions, due to wealth or poverty, conduce to lessen functional brain work, tend to impair intellectual capacity to think, and the ethical sense to do right. In the idle wealthy ranks and in the idle poor ranks we find most degeneracy. The active, industrious middle class carry the main current of improvement. Improvement is only found where there is activity, and degeneracy is always an accompaniment to idleness. Society sloughs off at its two inactive idle extremes. If you study the conditions that lead to brain work on the one hand, and those that lead to a cessation from brain work on the other, you have much of the secret of improvement and of degeneracy, in the individual, in the family, in the community, and in the nation. There is in this way a very

ready, because a very physiological, explanation of much that otherwise is strange and difficult to understand. Families lapse from wealthy positions into poverty in the course of one or two generations, because the necessities for brain work having been removed, degeneracy comes with the condition of inactivity. Races and nations readily follow the same course. A very large proportion of the incompetent and the vicious elements of society is made up of the lapsed members—of those whose lines of capacity point downward. Almost every family can be said to be tending towards survival or towards elimination, and the cause of their tendency can be readily learned by observing whether their brain habits are active or inactive.

The competitions of active, industrious society determine the levels of its members. The incompetent poor classes become poorer, occupy unfavorable and unhealthy positions, and eliminate rapidly; while wealth induces idleness and degeneracy, and consequent inability to add to, or to even hold to the property that parental or ancestral capacity may have provided; in time the rich disappear, or "the top rail goes to the bottom," to be eliminated in the poor ranks. In our rapidly changing American society, it is very common to find in the second or third generation the relics of once wealthy families, unable now to compete successfully for a living because of degeneracy in intellectual ability, and with ethical habits alongside the very lowest.

I have probably said enough to warrant the statement that brain activity alone induces brain capacity, and that brain inactivity induces brain incapacity.

In this observation, we notice that there is only one way of improving capacity, namely, by activity; but when we turn to the converse proposition, we recognize there are several ways of lowering it. Inactivity, I have said, induces most of the incompetency, but it does not produce all. It does it by impairing the brain's ability; but the brain's ability is also lowered by whatever else, in any other way, impairs or injures its structure. Functional capacity depends upon structural integrity. Any defect, injury or disease of the brain lowers its capacity; and we judge the pathological disability by the same tests that we use in grading physiological disability; that is, we witness there is always more or less impairment in intellectual and ethical capacities in brains pathologically impaired. In all our insane asylums we find persons who once were graded high in intellectual and ethical abilities, now sadly lowered in both these qualifications. We estimate the insane by the same tests we estimate the sane. In a large majority of cases the decision is easily made. It is only in those cases when the insane degree of disability is not yet quite reached, but is approaching,

and it is necessary to anticipate it, and in those cases when the disability is transient and questionable, that the expert is required.

The methods of brain degeneracy I have thus far mentioned are, foremost and principally, brain idleness, and next, those pathological conditions which are the results of disease, injury or defect; but there are other causes at work in society, by some not recognized or classed as pathological, which question I won't stop to discuss; and these causes, in my opinion, are very potent—probably, next to brain idleness, the most potent in modern brain degeneracy. I allude to the widespread and abundant use of brain drugs, the principal one of which is alcohol. Next to brain inactivity, I believe brain injury with drugs, especially alcohol, produces most modern brain degeneracy. In proportion as the amount of alcohol in the circulation is increased, in addition to a lessening of sensibility, we witness a gradual lessening of intellectual ability. This declines through descending stages from the condition in which we describe the person as a "little off," intellectual capacity slightly lowered, judgment and accuracy of thought slightly defective, to that condition where there is entire loss, and the man is a temporary dement.

In proportion, too, to the amount of alcohol taken, we witness ethical ability to be lowered, and the cerebral disability in this particular will be exhibited in descending stages, reaching from slight loss of the sense of propriety and decorum to that condition in which the person is such a nuisance, or is so degenerate to his associates, that he reaches the degree of temporary mania, and has to be restrained.

These effects of alcohol upon the brain will vary in different persons. Callous brains exhibit impairment to a degree than more sensitive ones; low grade brains reach the savage level sooner than highly advanced ones, and defective, injured or diseased brains exhibit their failures in the lines of their deficiencies.

The length of time, also, that the alcohol use is continued increases the degree of disability. A single debauch can be readily recovered from, but long-continued use leaves such impairment that only in rare cases does complete recovery ensue.

Sometimes we have these conditions all supervene in the same person; that is, we have a considerable quantity taken by a brain already weak or defective, and the drinking is continued a long time. This is the case with the majority of those whom we call inebriates. In a majority of cases the brain of the inebriate is originally low-grade, and nothing could be done to more effectually lower its capacity still further. But it matters not whether there is original weakness or not, a sufficient quantity, long continued, will bring down, in intellectual and ethical capacity, the

most advanced brain to the level of the lowest. Whenever an idle, incompetent brain is rendered still more incompetent by the chemical effect of a drug, degeneracy and the consequent elimination of the person and his lines of descent is rapid indeed; and this happens not nearly so much by the injury to other structures and organs of the body, so as to induce death directly, but, because the injury to the brain places the person, by his loss of intellectual and ethical capacity, in unfavorable, poor and vicious surroundings and indirectly causes the elimination of himself and his line.

Brain injury with drugs produces a great deal of modern brain degeneracy, and, in connection with brain idleness, is an exceedingly rapid eliminator in society. The popular and indiscreet use of alcohol, nicotine, opium, and similar drugs, is a very potent factor in modern degeneracy.

The application of the above principles to the explanation, on the one hand, of success and survival, and on the other, of failure and elimination, is very interesting.

We are very apt to lose sight of the rapid rate of human elimination. What is a possible or normal rate of increase is never reached by any people; causes of elimination are constantly at work to keep the increase below the normal rate. If every human female who is born reached adult life, and bore a reasonable number of children, directly, there would not be standing-room in the world. The grade of brain ability, as I have said, is the factor that, more than anything else, determines a person's position in the world; and a physiological consideration of the causes that lead to increase or decrease of these faculties is seldom heard; yet it is a most rational way of dealing with the subject.

Before I close, I think it will prove interesting if I apply some of the physiological principles I have been enumerating to a broader field, and as briefly as possible show how the rise and fall of races run on the same principles that individuals rise and fall in society.

A race is an aggregate of similar individuals—or, more properly, of similar lines of descent. What determines the grade of a race is the level of the aggregate capacity of these lines. The centre of the aggregate potentiality of the race, in the progress of its social dynamics upwards or downwards, varies as an individual's; with, of course, less sudden variations, because of the overlapping of generations—still it never, or seldom long, remains at the same level. Just as much as with the individual, it takes continuous activity to keep up capacity in the race, and inactivity lowers capacity.

We often hear it stated that a race or nation degenerated because they forgot the instructions or accumulated experiences of their forefathers.

The forgetting or the not heeding had very little to do with it. The records of the accumulated experiences of a race's previous history are always abundant, and the alarmed, but gradually thinning ranks of their leaders are continually proclaiming and preaching and teaching them; but the secret of their gradual decline in prestige and power, and comparative influence among other races, lies, as is often the case with the individual in society, in gradual abatement and stopping of previous brain industry and activity. An active race soon reaches a stage of comparative excellence and wealth and power, so as to be relieved of the immediate competitive necessity for continued exertion. When this is the case, it is just as much "human nature" in the aggregate of individuals, as in the single individual, to stop further exertion and exercise.

The ancient Semitic races, who once inhabited western Asia and ancient Egypt, and who long antedated the Aryans of Europe in civilization, grew powerful first and then rich, stopped activity and declined in excellence.

It matters not whether you locate the origin of the Aryan races in the centre of Asia or in central Europe, as is more recently advocated; when first known, they were an active, combative, competitive people in Europe, considered by the ancient Assyrians, Phonicians and Egyptians as barbarous and semi-civilized. Those Aryans who occupied the peninsulas of ancient Greece and Italy, caught up first the civilizations of Asia and Egypt, because they were nearest to them. An active, progressive, advancing race, like the individual, is acquisitive of knowledge as well as wealth. They learned from their advanced neighbors, and by activity themselves became powerful in knowledge and resources; then conquered and plundered the old Semitics, and rose to be the excellent and leading races of Greece and Rome. Greece, the one nearest to the Semitics, improved first and declined first.

In time, the same physiological processes took place with the people of Greece and Rome. They waxed comparatively excellent, the necessity for further exertion was relieved, and they turned the pinnacle of excellence and began the decline of the other side because of brain degeneracy—not because they had not the accumulated wisdom and wealth of the world, but because the aggregate of their brain capacity lowered in level for the want of the continued brain practice and exercise necessary to keep them up. The aggregate capacity of the nation to think and to act ethically declined.

Defended by the mountains to the north of them from their kindred Aryan races of central Europe, and having thoroughly demolished the races south of them, the Empire of Greece, and of Rome particularly, had abundant time of idleness and inaction to become thoroughly degener-

ate; so, when the hordes from the north poured over the mountains, these empires sank easily. The darkness that followed the submergence of these ancient civilizations, was for a time so complete and dense, because the Goths and Vandals were themselves not able to appreciate and appropriate the civilizations that they destroyed. They conquered Rome too soon, before they were themselves ready for it. "The dark ages" were the result; and if it had not been for the Arabs in Alexandria, who worked round the coast of North Africa, and into Spain, keeping up the lamp of civilization, with the help of the Jews and Greeks they imported to teach them, the light of civilization would have been almost totally submerged. The Moors of Spain took eventually the same old routine course, before the gradually improving Aryans of central Europe; in their turn became rich, inactive, and disappeared.

Those Aryan nations of Europe who to-day hold their positions of highest excellence in the world, have solely reached their eminence by their improved brain abilities—the result of generations on generations of advancing brain practice.

A semi-civilized king of Asia or North Africa may think in his visit to London, if he had all the wealth and vast material resources of England transported to his country, his would be a nation equally as great. Nothing is more mistaken. The only way for his people to reach the proud eminence of excellence of the British Islanders, is for them to have gone through the same long processes of industrious, persevering, high-ordered brain practice, similar to that through which these people have passed. It is the work of generations, and cannot be donated in a day.

In this connection, it is interesting to notice to what degrees and at what levels the different savage, barbarous, semi-civilized races of the world have appropriated the civilization of Europe, as it has, in the intercommunication of modern commerce and travel, and by teachers, been conveyed to them. There are hundreds of illustrations in the world of the fact, that a low grade race accepts and runs advanced civilization just at the level of their inherent ability. A singular observation, connected with this fact—often some test of competitive ability, in war for instance—is necessary to show the superiority of the advanced race to the inferior one, so as to make it ready to appreciate and learn.

The inhabitants of the Pacific and Indian Ocean Islands are good illustrations of these principles. Those inhabitants, who by ethnological tests show themselves to be descendants of the more advanced races of Eastern Asia, have appropriated civilization at more rapid rates than those types similar to the races of Southern

Asia and Africa. At one extreme, we may mention the notable examples of the Sandwich Islanders and the Hoovas of Madagascar, both of Eastern Asia types; and at the other extreme, the Andaman Islanders and the inhabitants of Tasmania and New Zealand, of African type. Of the Eastern Asiatics, the Japanese exhibit, in all particulars, more activity, and consequently more progressiveness, than the Chinese, the Malays or Burmah races. The ancient civilizations of these races were among the first in the world, but, in the case of the Chinese particularly, the rigidity of too crowded a population suppresses improving activity.

I could take the range of the world to illustrate these principles, but have not the time. It may prove more instructive to come closer home.

In America we have three very distinct types of men—the Indians, the Africans and the European whites.

It is a remarkable fact, low-grade races melt away and disappear in the presence of the more advanced ones. In modern times they are not exterminated by war; very few are killed out; still, they rapidly disappear. Whole tribes contiguous to the English and European colonies in Africa have disappeared, and in Australia they are melting away like our Indians. The last Tasmanian has been said recently to have died, and the English government, out of sympathy, has recently been gathering together the few natives of New Zealand as ethnological curiosities.

When an advanced race, as the Europeans in America, for instance, occupy the country of a low-grade race, and attempted to force them to assume the methods of civilization, the change of the brain habits of thought is too sudden for the inferior race to assume. In civilized society, as I have shown, persons of low intellectual and ethical abilities occupy the eliminating grades. To force an inferior people, never practiced or trained in the habits of industrial competitive thought, into the ranks of a civilized race, is equivalent to forcing them into the eliminating grade of that society. The Indians have nowhere been able to enter into industrial competitive life with the Europeans and survive, but, wherever it is attempted, they simply assume the position they are capable of taking; in common language, they become poor and vicious, and are eliminated along with the eliminating whites. The vice of civilized society, to which they take with avidity, is alcohol drinking; and nothing contributes more rapidly to increase their incompetency and viciousness. As with low-grade individuals in advanced society, alcohol is a most rapid eliminator of low-grade races. The general government, in its management of the Indians, finds it has to prevent their access to alcohol, and the missionary among them, in his

endeavors to arrest the current of their downward degeneracy, finds his efforts futile, if drink is allowed. The elimination of the Indian races is due principally to these causes; first, it is impossible for the Indian to assume so suddenly the habits of civilized thought which are necessary in order to prevent elimination. For the same reasons the hyena and eagle in confinement become unprolific and defective in descent, so does the Indian; and he often adds rapidly to his degeneracy by drink habits.

When the Spaniards discovered America, they set out at once to enslaving the Indians. They did this first on a large scale in the West Indies, by the hundreds of thousands. The sudden change of brain habits was so severe and extreme that these races exterminated excessively. To-day there is hardly a relic to be found. They proved so unsuitable for slaves, the Spaniards had soon to import Africans.

The Africans, from the remotest antiquity, have been preyed upon by other races for slaves. From the eastern side of the continent, next to Asia, they have been raided most, and are still so to day. On the west coast, whence America received her slaves, they had been before that for thousands of years unmolested and least mixed with Asiatics. They had, among themselves, varied to some extent into grades, according to activity, climate and surroundings. The lowest types of men in the world were found among them, while some were somewhat advanced. The characteristic that rendered them suitable for slaves was, they were passive in disposition, and would bear pressure and moulding. After African slavery had begun in the West Indies, it was soon extended to the continent.

The two hundred years that slavery continued in the United States under its extreme artificial conditions, it exerted powerful modifying influences upon both the Africans and their European masters.

The Africans, for four or five generations, underwent forcible practice in very much more advanced brain activity than they ever performed before. The African, originally, with very moderate exceptions an abject savage, was rapidly made to assume the language, dress, customs and conventionalities of the whites, and practice their habits of thought as far as he was able to understand and imitate them. Each one may be said to have had a private tutor of his own. It is true, the master's interests directed and largely controlled their brain practice; selfishly, in many cases, he directed his slave's habits and labors; still, involved in all such work, was brain exercise of a higher order than the African ever practiced before. His muscles were exercised, his food directed, and his improved sanitary condition brought his average general health to a higher level. At the time of their emancipation

there could not, in my opinion, have been found in the world six millions of people, in a body, to excel the American slaves in three essential particulars—general healthfulness, prolificness, and sobriety. These excellences were the results of two or three hundred years of artificial selection and improvement. In brain work, higher intellectual and ethical practice and instruction was the result of simple association with the whites, as well as the result of direct efforts on the part of the whites to improve them. The selfish interests of the whites dictated, probably, most of their efforts; still, some were incited by the highest altruistic motives. Upon the whole, the American negro emerged from slavery improved above his original grade in intellectual and ethical capacities; and his was an example of more rapid advancement than has ever been witnessed before in such a type of people in such numbers.

The national processes of improvement by activity, and of deterioration by inactivity, had obtained to some extent among the tribes of Africa, which made slight variations in the types imported as slaves, and probably still hold in the grades among them; but the artificial and forcible influences which obtained all during slavery, by training, association and education, and are still continuing, in the efforts made to improve and govern them, together with miscegenation, have tended to advance some few lines toward comparative ability to compete, and toward continuance and survival; but the large majority are taking their natural level in the eliminating grades of society, and prove an incubus upon the country's progress. The race is certainly letting down in the three particulars in which they excelled—of healthfulness of system, of prolificness, and of sobriety. Among those, braced up by, and floating along with, the currents of activity established and maintained by the whites, most examples of improvement are found. But in these sections, where they are in large majorities, and left to their own exertions, intellectual and ethical deterioration is very apparent. Statistics show very rapid elimination of them in the towns and cities, where competitions with the whites force them into most unfavorable surroundings.

That the negro, in the South, is seen to fill the prisons, the police courts and the penitentiaries is an exhibition of a natural condition; he is living under a civilization and a code of laws that he is not able himself to formulate or maintain. He fails ethically, as well as intellectually, in larger proportions than the whites, because he is not as capable in maintenance of the kind of activity his surroundings demand. But I have not the time to pursue this question further.

It is only necessary, generally, in the case of the European whites in this country, to apply

these principles, to have ready solutions of the changes going on in our different communities and in our national society. The wholesale importation of the degenerating classes of the old world is having a most deteriorating influence upon our national, intellectual and ethical level. As the good of society feels the fluctuations in the ethical currents first and most, we can see the deterioration, even in high places, due to this influence. Brains degenerated in capabilities, by the rigidity of the strata in European society, which prevents all kinds of activity, except muscle drudgery, are filling our land faster than the three or four generations necessary to elevate them can counteract. We have not yet invented a cerebral dynamometer by which we can quickly test a man's intellectual ability and his ethical strength. Such a test, however, is sadly needed. Persons who fall below a certain level in these two essential qualifications ought not to be allowed to enter the country, no matter whether they hail from Europe, Asia or Africa.

In conclusion, I insist I have been on purely physiological and professional ground all the way in this discussion. The corollaries I would draw from it are:

1. Brain capacity is solely the result of ancestral and individual brain practice.
2. The test of these qualifications are the grades of intellectual and ethical abilities, usually determined by the level the individual, the family or the race occupies in competitive life.
3. Degeneracies of brain ability are occasioned by brain inactivity, which is the principal method of deterioration; but whatever injures the brain structure impairs intellectual and ethical ability, whether it be traumatism, disease or defect, or abuse with drugs.
4. A great field for the highest order of public sanitation is open in this direction, heretofore almost wholly unoccupied by our profession.

In discussion Dr. Herdman, of Michigan, said:

I, for one, feel like congratulating the members of the Section upon the privilege of listening to such a philosophical paper as has just been read. It seems to me to have presented topics eminently appropriate for consideration by this Section. It is a deplorable fact, disheartening oftentimes to the neurologist and alienist, that many of the diseases with which he has to deal in his daily practice are, in the individual, incurable; but little can be done for them in one generation. The causes and influences that have been at work in bringing about the pathological change are inherited from the ancestor; are the fruit of bad social customs, of imperfect methods of education.

The work of the neurologist, therefore, as a student of brain deterioration, carries him beyond

the immediate to a study of remote causes, which are the chief factors oftentimes in producing the result in the individual he is called upon to treat. Upon us rests the responsibility of pointing out these far-reaching influences, and herein is the most encouraging field for the exercise of our talents as promoters of the welfare of humanity.

It is true, as has been clearly set forth in the paper, that man, in his evolution to the point of greatest efficiency, can only attain that end by healthful exercise of every faculty. Man's constitution is a trinity composed of *physical*, *mental* and *moral* faculties. The perfect man is the product of these three acting harmoniously and carried to the degree of their highest possible development. They constitute a tripod on which the superstructure, when symmetrically built, rests securely. And in the process of development toward the perfect man no one of the three pillars, upon which the final result depends, can be ignored. To neglect the physical, the mental or the moral faculties of his nature; to cultivate one at the expense of the other; to fail to observe the interdependence of the one upon the other, will produce a greater or less degree of deformity, and not the perfect man. The central nervous system is the organism upon which the development of these faculties depends, and by means of which they find expression. The growth of the normal structure and function go hand in hand. What then, we should ask ourselves, are the causes, the influences at work in the race and in society; what are the conditions necessary for obtaining perfection in the harmonious development of man's threefold nature?

These are legitimate subjects for the thoughtful consideration and research of every physician who attempts to enlighten his fellow-man as to the laws to which his nature is subjected, and the forces that affect his well-being in its entirety. And such responsibility rests upon the neurologist and alienist, perhaps to a greater degree than upon any other class of practitioners of the healing art. In him do we expect to find a storehouse of all truth, so far as discovered, which has a bearing upon the evolution or dissolution of man's brain. What then is the value of the discussion of this or that agent in the pharmacopœia in some particular disease, as compared with a study of these principles, which underlie an entire class of pathological conditions?

There is at the present time a strong conviction among neurologists, which is shared by others in the medical profession and by thoughtful men and women among the laity as well, that the man addicted to the use of alcohol in excess is a sufferer from disease; that his brain has undergone functional, if not structural, change, which renders him as incapable of self-control as the idiotic or the insane, and that this condition of irresponsibility is not confined alone to those

times when his blood is saturated with alcohol from recent indulgence or debauch—but that during the intervals of drunkenness he is incapable of acting as a sane man, and should therefore be dealt with, not as a criminal to be turned over to the police only in some fit of bacchanalian excess, but is at all times, until pronounced cured by competent judges, a fit subject for the hospital or the asylum.

This and other social problems of no less import and wide-reaching applications, come within the legitimate range of our purpose; are rather the most vital questions for discussion by the members of this Section, and the paper which has just been read points out the road along which, as a company of specialists, we can do the greatest good to our fellow-men.

Dr. Hughes said he desired to express his appreciation of the worth and excellence of the paper. He was glad to see papers of this kind brought before the Section. Formerly physiological psychology was a subject that emptied the room, but this to a great extent had been changed by Maudsley and Spencer. These writers had attracted general medical attention. Papers of this kind will do much to settle psychical hygiene for both the individual and society.

THE VIRILE AND OTHER NERVOUS REFLEXES.

Read before the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, held at Washington, D. C., May, 1891.

BY C. H. HUGHES, M.D.,

OF ST. LOUIS.

PROFESSOR OF NEUROLOGY IN MARION-SIMS COLLEGE OF MEDICINE, ETC.

In a previous communication on this subject (*vide Alienist and Neurologist* for January, 1891), I have called attention to the fact that in a perfectly healthy individual, whose spinal cord is entirely normal, especially in its genito-spinal center, placed supine on a couch without head-rest, nude about the loins, the sheath of the penis made tense by claspings the foreskin with the left index finger and thumb at about the place of the frænum, and pulling it firmly toward the umbilicus, placing the middle, ring and little finger low down upon the dorsum of the virile organ, the dorsum or sides of the penis, near the perineal extremity, then sharply percussed, a quick and very sensible reflex motor response or retraction of the bulbo-cavernous portion will be felt to result from this sudden percussional impression, like that which follows, though less pronounced, in the testicles, after sensory irritation of the inner aspect of the thighs, and known as the cremasteric reflex, with this difference only, the cremasteric reflex is a sudden upward movement of the testicle of the side irritated,

while the virile reflex is a sudden downward jerk. While this reflex, like all reflexes with which I am familiar, is away from the irritating afferent impression, it is in marked contrast with the patellar tendon phenomenon in being away from the heart instead of toward it, as so many reflex movements are. It differs from the ordinary penile erection, and must not be mistaken for it (for it cannot properly be called an erection) in this respect, too, viz., that it is downward, and not upward, and proceeds always from a peripheral and external irritation; whereas, erections more often proceed from direct central (cerebral) impression proceeding downward and outward.

Its action corresponds to the œsophageal reflex, or reflex for swallowing.

This reflex symptom is of important clinical and physiological significance, as will later on be shown.

I have called it the virile reflex, because I think, if properly sought for, it will be actively present in all healthy adult males with normal spinal cords; at least, I have so found it in all. It is absent in infants, and feeble or absent in male children who have not attained the age of puberty.

A number of years ago I ventured the assertion that the absence of the cremasteric reflex would be found of significance in the determination of impaired virility from sexual excess or masturbation. This, subsequent experience has only confirmed. Now this new sign—the virile, the penis percussion reflex, or, as M. Ounanoff calls it, the bulbo-cavernous reflex—present, impaired or absent, gives us another valuable evidence of the vigor, impairment, loss or abeyance of the sexual powers in man.

After prolonged excessive venery it becomes impaired or disappears, to return again with sexual recuperation.

After excessive masturbation, long continued, with accompanying neurasthenia, I have found it impaired, but seldom entirely absent in young subjects. It is not impaired in masturbation when the habit has destroyed the sexual power. It disappears in some cases of chronic meconism, and becomes abeyant in long and beastly intoxication, though often excitable in acute alcoholism. This subject needs further investigation.

It is lowered and abeyant in the later stages of typhoid fever, and I have found it also in the moribund state. I have found it absent in old men who have acknowledged and sought treatment for entire virile incapacity.

It is often, but by no means uniformly, found in sympathy with the other reflexes in spinal cord disease of the lumbo-dorsal spine, as the quadriceps extensor femoris tendon reflex, the anal, vesical and cremasteric reflex, the Achilles reflex, ankle clonus, etc.

This phenomenon may also be elicited by sud-

denly jerking the foreskin after it has been made tense, or by pinching the theca of the penis when it is in this stretched condition. This reflex may be reinforced like the knee phenomenon, but by a different process, viz., the frictional excitation of the glans and body of the organ by means of a brush, or brushing it briskly with a piece of paper. It may also be evoked by electrical excitation, a kind of clonus sometimes appearing after this form of irritation. As I said in my first communication, some skill in palpation—a sort of tactus eruditus—is necessary in examining for this sign, the characteristic jerking back of the bulbous urethra within the sheath of the penis being felt only when carefully sought for. It is not ordinarily to be seen.

I have found the sign absent in cases like the following: Pupils unequal, patellar reflex exaggerated, and other evidences of sclerose in plaques, with history of syphilis, and acknowledged feeble virility, and diagnosis by a competent ophthalmologist of optic atrophy. I believe it will be found to be quite generally absent when there is optic atrophy, unequal pupils, and other evidences of cerebral sclerosis, or multiple cerebro-spinal disease of this nature. I have found this sign absent in the status epilepticus, but not necessarily modified in hemiplegia, and exaggerated in cerebral paraplegia.

The following clinical records, made since my first report on this subject, add additional confirmation to the significance of this sign:

Case 1.—Mr. J. B., aged 23, single, locomotive fireman, first presented himself for treatment at my office July 11, 1891, when I obtained the following history: Some three years ago, in alighting from his locomotive running at the rate of 15 miles an hour, he sprained his back, but it did not give him much trouble at that time. About three weeks ago, while perspiring freely, he “caught cold” and the perspiration suddenly stopped—from this patient refers present trouble, though he had an attack of la grippe in February, and about latter part of April, he noticed impairment of motion of right leg. Some four years ago he indulged in sexual intercourse to excess—upon one occasion, had connection seven times in twenty-four hours. He has had no inclination for sexual intercourse lately, thinks he has had sexual desire but about a half dozen times during the past two years.

Bowels constipated, for which he resorts frequently to purgatives. Had an attack of vertigo to-day, and fell to the floor while in the act of yawning. Pulse (sitting) 66; upon slight exertion (walking about the room), pulse increases to 78. Right knee-jerk abnormal; R. quadriceps clonus marked up to origin of muscles—a slight tap below right patella (not sufficient to produce patellar reflex), will cause quadriceps muscle to vibrate. R. knee response below normal, left

knee-jerk impaired, no quadriceps clonus. R. gastrocnemius reflex normal; R. plantar and solar reflexes exaggerated, and clonus follows reflex excitation; plantar surface of right foot hyperæsthetic. Flexion of right foot incomplete one half, rotation impaired one-half, flexion and extension impaired about one-half. While sitting, he can only lift right leg and thigh about three-fourths as compared to left. Has head and back ache. No spinal tenderness, tender over crest of right ilium and beneath ribs of right side.

Æsthesiometric tests of finger tips give normal results. Numbness of left great toe, but no abnormal æsthesiometric sign. Has slight right scrotal hernia; has phimosis.

Virile reflex impaired, extremely feeble, and elicited with difficulty. Patient put upon the following treatment:

R. Quinæ bisulphatis, drachm ij.

Ext. nucis vomicæ, gr. xij.

Ergotine, scrup., ij.

Ext. belladonnæ,

Aloin (Merck), ãã gr. iij.

Liq. potass. arsenitis, gtt. xv.

Misce, et fiat cap., No. xxxvj.

Sig. One three times a day.

R. Sodii bromidi, oz. iss.

Aq. menth. pip., q. s. ad. oz. vj.

Misce, solve, et Sig. Tablespoonful at night.

Patient reported some three times at intervals of a week, and a marked improvement was observed. He then left on a trip, to return unless the improvement continued uninterruptedly, and I have not heard from him since.

Case 2.—Mr. Chas. E. H., 21, occupation farmer, single, applied at my office for treatment August 15, 1891, and gave the following history: About a year ago, he slept on the damp ground for five successive nights, each morning he felt stiff, and head was very sore. As the effect of this, he was sick in bed with fever for a week or more, legs were paralyzed, bowels constipated, and urine retained—was catheterized several times. He was attended by two local physicians. Says he suffered severe pain during first three weeks of illness, and was troubled with erections. Patient's present condition is as follows: Pulse 90 (patient sitting) and full, temp. 100° Fah., appetite and digestion good, and sleeps well; no erections at present. Some pain in lumbar and sacral region. Crosses right leg over the left with difficulty, cannot lift leg without the assistance of hands, cannot stand alone. Patellar tendon reflex is absent, virile reflex present, but impaired, cremasteric reflex normal, and has abdominal reflex. Has never had syphilis, or any zymotic disease.

Patient placed upon the following treatment:

R. Quinæ bisulphatis, drachm ij.

Ext. nucis vomicæ, gr. vj.

Ext. ergotæ, gr xxiv.

Fowler's sol., gtt. xl.

Misce. Tiat. cap. No. xxiv. Sig. Take 2 capsules three times a day—in the morning, after dinner, and at bedtime.

R. Sodii bromidi, oz. iss.

Kalii iodidi, oz. ss.

Syr. Hypophos. comp. (Fellows'), oz. iv.

Liq. pot. arsen., dr. j.

Aq. menth. pip., ad., oz. vj.

Misce. Solve, et Sig. Teaspoonful in the morning and 2 teaspoonfuls in the evening.

I select and epitomize a few cases from my earlier records as follows:

The first three were middle aged, of these, the first was married, and gave a history of syphilis, brewer by occupation, erections feeble, white atrophy of retina, unequal pupils—left larger than right, vision obscure in both eyes, cerebro-spinal sclerosis (multiple and lateral).

The second gave a history of former syphilis, though at time of observation he was in good flesh and general health excellent, miller and merchant, lives in country; impotent—seldom has erections, but at times has good erections and completes the sexual act.

The third is impotent, fails to have erections.

The next two are children under twelve years of age; of these, the first is a country boy and has epilepsy mitior, the second, also a country boy, has epilepsy gravior.

Another case was that of a civil engineer, single, aged about 28, with nocturnal epilepsy from excessive masturbation.

Additional experience since the discovery of this important diagnostic sign only confirms the conviction uttered in my first paper, viz.: It should receive further consideration at the hands of neurological clinicians, for it appears worthy a place in clinical neurology with Westphal's paradoxical contraction, Erb's reaction of degeneration, or any of the hitherto recognized diagnostic reflexes, or clonuses.

I have found an analogous reflex to this phenomenon in healthy females.

It may be elicited in normally vigorous persons when that condition of the organ is present that we find coëxistent with a desire for coitus, when the sexual act is about to commence, and shortly after coitus, if the sexual desire has not been gratified to satiety. It can be evoked during priapism, and during penile relaxation, if power for a second coitus remains in the organ.

In conclusion, I think we are on the verge of further most important discovery in the direction of physiological and pathological reflex phenomena, and on the verge of an enlarged comprehension of their value in diagnosis and prognosis. I believe that every part of the body supplied by an afferent (sensory) nerve communicating with a center, whether cerebral, spinal or ganglionic, capable of an efferent or motor response, will be found susceptible under appropriate stimuli (electrical, mechanical, or special) in normal or pathological state, responsive in some way, and that

this plus or minus responsiveness is yet to have far more remarkable value in clinical estimation than is now accorded it or dreamed of in medical minds. For instance, in our clinical investigations, we take into consideration such purely physical reflexes (in addition to the cardiac and visceral movements) as the palpebral, pupillary, naso-pharyngeal, vesical, cremasteric, anal, and the tendon reflexes of the lower and upper extremities, normal and abnormal, and the clonuses which are of the nature of reflex phenomena prolonged into rhythmical movements.

Many of these are more or less influenced by conditions of psychical inhibition.

Then we have in disease often to consider the state of the psycho-physical reflexes, as the involuntary shedding of tears, unintentional, or causeless weeping, involuntary and unsuppressible laughter, shouting, involuntary exclamations of various kinds, as of fear, disgust, joy, etc., and sudden involuntary and unrestrainable psychomotor responses of various kinds, virile erections under erotic psychical impressions. These latter are downward influences, reflex responses from psychical excitation through peripheral impressions transmitted through sight or other senses, or originating altogether in ideational center. Then we have the psychical responses to peripheral impressions, such as the sudden mental states and expressions following physical impressions, like the immediate outcry of peripheral pain—the true nature of a reflex phenomenon wherever we find it being a peripheral impression transformed into an immediate, or almost immediate, motor response or expression.

If we take into consideration how much of our power for regional diagnosis has been aided within the past few years by what we already know of these reflexes, especially of the knee jerk, Achilles reflex, the foot clonus, the anal, vesical, cremasteric, and virile, how much more may we not hope for with confidence, if we but persevere in our search for yet unknown manifestations of these phenomena? I have already elicited in certain moribund states, an oral reflex, as heretofore announced, and a physiological anal reflex; and have confidence even before its announcement, not knowing it was new, much that Rosolimo asserts concerning the reflex of the anal sphincters, this latter reflex serving as an especially valuable differentiating test where sexual failure is to be early distinguished from commencing vesical or rectal paralysis.

A CHEAP DISINFECTANT.—The nitrate of lead is the cheapest disinfectant known that fulfils its intent. It does not, however, prevent putrefaction. The chloride of lead is much more effective in all directions. It is made by dissolving a small teaspoonful of nitrate of lead in a pint of

boiling water; then dissolve 2 full teaspoonfuls of common salt in 8 quarts of water. When both are thoroughly dissolved, pour the two mixtures together, and when the sediment has settled you have 2 gallons of clear fluid, which is the saturated solution of the chloride of lead. A pound of nitrate will make several barrels of the liquid. The nitrate of lead costs from 18 to 25 cents a pound at retail.—*Med. Bulletin.*

THE JOURNAL OF BALNEOLOGY.—It is announced that Dr. J. N. Bell, of Brooklyn, Dr. Frank Woodbury, of Philadelphia, and Dr. Geo. H. Rohé, of Baltimore, are to be the editors of this journal, in the departments of balneology, dietetics, and climatology, respectively.

PULMONARY TUBERCULOSIS TREATED BY HYPODERMIC INJECTIONS OF ARISTOL.

On Sept. 15, 1891, M. Herard read before the Paris Academy of Medicine, a report by Dr. Nadaud, upon this subject. An abstract of it is printed, as follows, in *La Semaine Medicale* (No. 46):

After having observed the excellent effects of Aristol upon scrofulo tuberculous lesions, and found that Aristol was perfectly innocuous in internal medication, M. Nadaud decided to make use of hypodermic injections formulated as follows:

Oil of sweet almonds (sterilized) 100 c.cm.

Aristol 1 c.cm.

The solution should be filtered.

Nadaud's first injections were made upon a child, aet. 7 years, who, after an attack of coxalgia, had developed several abscesses followed by fistulous tracts. One cubic centimetre of aristol was injected daily. After twenty-five days of treatment there was no trace of suppuration to be seen.

In consequence of this result, Dr. Nadaud decided to test the value of hypodermic injections of aristol in the treatment of pulmonary tuberculosis.

Twenty-three patients suffering from tuberculous lesions of the lungs were successively treated by injections of aristol without any other medication whatever.

In seven cases the amelioration was so great as to induce the belief that complete cures had been effected. The treatment covered from twenty-five to thirty days. The amelioration has continued up to the time of this writing, *i. e.*, from three to four months.

In five of the twenty-three cases there was a prompt amelioration, but, a month after the cessation of treatment, some symptoms were observed which seemed to call for a second series of injections. Generally, the relapse was of slight importance, and the patients in this category soon resumed their habitual occupations. In no case was it necessary to make a third series of injections.

The rest of the cases are still under aristol treatment.

In concluding his paper, Dr. Nadaud said: The effects of aristol are promptly observed usually on the sixth or seventh day of medication and are first manifested by a diminution of the cough and a suppression of the night sweats.

After twenty or twenty-five days of treatment we generally find that the patient has increased in weight.

Aristol gives its best results in the first and second stages of pulmonary tuberculosis. The injections do not cause inflammation, irritation, abscess, eschar, or induration.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.
PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE.,
CHICAGO, ILLINOIS.

All members of the Association should send their Annual *Dues* to the *Treasurer*, Richard J. Dunglison, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, NOVEMBER 7, 1891.

TRICHINOSIS TREATED BY FOWLER'S SOLUTION OF ARSENIC.

In the New York *Medical Journal*, September 19, is reported a case of trichinosis treated by FOWLER'S solution of arsenic, with recovery. The reporter is DR. W. H. MERRILL, of Pepperell, Massachusetts, and the patient was an inmate of the Ward's Island Hospital, an Italian immigrant aged twenty-five years. The cause of the disease was believed to be the ingestion of Bologna sausage, which took place about twenty days before the admission to hospital; the partaking of the sausage in this instance, more than any other former ones, was emphasized by the fact that the man was made unwell by it; he had vomiting, diarrhœa, anorexia and gastric pain, also later some hoarseness and cough. At the time of admission, the muscular and articular symptoms strongly favored the diagnosis of trichinosis, which was confirmed on the second day by the harpooning of a muscular specimen from the patient's right biceps. This exhibited an abundant number of trichinæ in their earlier adult form. None of the parasites had progressed to the stage of granular degeneration. A second muscular specimen was obtained one week later, and yielded the same appearances. In spite of tonic treatment, the patient's condition grew steadily worse for a period of ten days,

until his condition became decidedly precarious. A myositis of his masseter muscles had sprung up which rendered the reception and swallowing of food extremely difficult. The patient's urine was scanty, but showed no albumen and no sugar. The hot-air bath was used, together with some of the ordinary diuretics, and the quantity of urine passed in twenty-four hours was brought up from fifteen to forty ounces; and that was the average excretion during the remainder of the man's stay in hospital. FOWLER'S solution was given in five-drop doses, to be increased three drops per diem until the constitutional effects declared themselves. For two or three days after this treatment was begun the patient did not improve, and in fact seemed fatally ill; but on the fifth day some slight change for the better was noticed, in the return of appetite and some lessened rigidity of the jaw-muscles; and soon the pulse began to grow stronger. The pain and œdema about the joints then began to subside. The improvement during the next ten days was continuous and fairly rapid. The skin over the abdomen showed striæ, somewhat resembling those seen upon the abdominal integument of a pregnant woman, which extended downward and outward. The cause of these marks was obscure, since the patient had not had any hyperextension of the skin sufficient to account for such striation. The limit to which the dose of FOWLER'S solution was raised was thirty-six minims in twenty-four hours. The dose was intermitted or reduced whenever arsenical symptoms were reached. The author believes that this is the first case on record where arsenic was used for trichinosis, and he shows no inclination to base any far-reaching conclusions on this solitary case. But he publishes the results as being, to all appearances, sufficiently prompt and satisfactory to warrant others in making a trial of arsenic, in default of a knowledge of something better. The author suggests that the good effects of arsenic in his case were due to the germicide properties of the drug, and to the great facility with which FOWLER'S solution diffuses itself through the body. Arsenic not only increases the activity of capillary circulation, but over certain forms of cells exerts a power to compel retrograde metamorphosis. It is possible that some combination of these phases of drug activity may either destroy or abbreviate

the life of the parasite. DR. MERRILL devotes the closing portions of his paper to a rapid survey of the various drug treatments of trichinosis that have been most successful in Germany, where the recorded cases of trichinosis are far in excess of those of any other nation, and he does not find any drug that promises any better results than arsenic. Among the agents that have been tried have been alcohol, glycerine, the picro-nitrate of potassium, and the salts of calcium. FIEDLER has used large doses of glycerine, but experiments made upon dogs which had been fed upon trichinous flesh were found not to be benefited by that drug, even in very large doses. It would be interesting to see a similar line of experiments undertaken with regard to effects of arsenic upon infected animals.

THE HEART IN DIPHTHERIA.

It is well occasionally to have our attention directed specifically to an important symptom in a disease, particularly if that symptom be only occasionally manifested. Every practitioner knows well that sudden heart failure is liable to occur in diphtheria, and understands the importance of rest in connection with it, but it is to be feared that this knowledge of the subject is not always followed in practice.

The cardiac complications of diphtheria is the subject of an essay by DR. WM. C. DABNEY, of the University of Virginia (*Va. Med. Monthly*, October, 1891), in which he calls attention to three forms of cardiac disorder, accompanying or following this disease:

1. A rapid and feeble pulse, often irregular in force and rhythm. This is the usual condition during diphtheria, and not infrequently continues after the disappearance of the fever.
2. A feeble pulse, which becomes progressively slower until the beats number less than forty, sometimes less than thirty, to the minute.
3. A sudden failure of the heart when all other alarming symptoms have disappeared.

These two latter conditions should unquestionably be considered together. The one is suspiciously like a paresis; the other is certainly a paralysis. When sudden heart failure is recognized as one of the diphtheritic paralyses, its peculiarities are the more readily understood. While palatal paralysis is the more common form in diphtheria, nevertheless it is well known that

any other group of muscles may show the same result, or the paralysis may be general.

The conditions of the throat paralysis may be considered as applying to the cardiac failure as well, frequency alone excepted. The throat paralysis may occur at any period of the disease, but most frequently it is a so called sequel, although recent experiments have shown conclusively that the poison elaborated by the LÖFFLER bacillus may produce it. Similarly, the cardiac paralysis may occur either early or late.

A sore throat, so mild as not to inconvenience the patient at all, and for which no medical relief is sought, is followed by paralysis of the throat, and then for the first time is it realized that the patient has been suffering from diphtheria. Such mild attacks are by no means infrequent, and perhaps their principal lesson is to teach that as one form of paralysis follows such mild cases, so may another form, and that no case of diphtheria is so mild that the heart may be neglected.

The oftener palatal paresis is looked for in diphtheria, the more frequently will it be found. It does not always force itself on the attention by the regurgitation of liquids through the nose, but it is a little surprising to find how many diphtheritics show some nasal twang to the voice. This makes it all the more necessary to watch for the evidences of cardiac failure.

DR. DABNEY does not agree with this view that the slowing of the pulse is an evidence of cardiac paresis, but describes it in the following words: "In many cases which I have seen the earlier symptoms presented no special gravity, but after a week or ten days, when all false membrane had disappeared, the patients seemed to be on the high road to recovery, the pulse, which had been quick and feeble, would gradually become slower without any marked improvement in force. There was a gradual diminution in the frequency of the pulse from day to day—sometimes even from hour to hour—until it fell to forty, or even thirty beats per minute. The only other symptoms noticeable in the case were exhaustion and some degree of restlessness. In no case was there any paralysis of muscles, nor were there any other evidences of multiple neuritis. There was no irregularity of rhythm in the cases as a rule, nor was irregularity in the force of the heart's beat as marked as in the first class of cardiac complications."

The prognosis of the slow and feeble pulse is extremely unfavorable. According to DABNEY it is nearly, if not always, fatal, when the pulse drops as low as forty.

Absolute quiet, both mental and physical, and rest in the recumbent position, are to be regarded as the best prophylactic measures in these conditions.

In the cases of slow and feeble pulse, DABNEY reports that he has used strychnia, atropia, brandy, ammonia, ether, and the other cardiac stimulants and tonics, but without the slightest benefit. It may be suggested that in these cases eliminatives, acting upon the kidneys and skin, such as the alkalies, hot baths, and perhaps even acetanilide or antipyrine might be exhibited. This much is certain—prolonged rest after diphtheria, even if it has been of the mildest type, should be the rule.

OUR GREAT MEN.

The celebrations throughout the world of VIRCHOW's seventieth birthday, October 13, 1891, were merited honors to the great man who has shed so much lustre on medical science. Medicine delights to honor him, and he is no less pleased with the profession which made his great work possible. At the Johns Hopkins celebration of this event, PROF. OSLER took as the subject of his discourse "RUDOLF VIRCHOW, the Man and the Student." He says: "It has been a century of release—a time of the loosening of bands and bonds; and medicine, too, after a long enslavement, ecclesiastical and philosophical, received its emancipation. Forsaking the tradition of the elders, and scouting the Shibboleth of the schools and sects, she has at last put off the garments of her pride, and with the reed of humility in her hand, sits at the feet of her mistress, the new science."

Truly, no one has contributed more than VIRCHOW to the accomplishment of this result. Quite early in life he demonstrated his independence of thought, and lack of regard for existing forms, merely because they do exist, by taking part in the German students' revolution of 1848, and for his pains was dismissed from the minor positions which he then held in the University of Berlin. Was it good fortune that recalled him, or is it impossible to keep down such men?

His famous *Archiv* was started in 1847. With his development of pathological anatomy, and the influence of his work on professional thought, our readers, as physicians, are familiar, but it is not equally well known that his activity in other lines was no less marked than in this. Throughout his whole life he has worked in anthropology, and his contributions to the literature of this science have been numerous and valuable.

DR. OSLER quotes JACOBI, to show his work in archæology: "SCHLIEMANN, by whose modern witchcraft holy old Troy is just leaving its tomb, invited VIRCHOW to aid him in his work of discovery of the buried city. . . . But what has engaged my attention and interest most has been to observe the humanity and indefatigability displayed by the great man in the service of the poor and sick. To read of his constant, practical exertions in behalf of the miserable population of Hissarlik; how he taught the aborigines the efficacy of chamomile and juniper, which grow about them, unnoticed and unused, in great abundance; how a spring he laid open for archæological purposes has been called by them 'the physician's,' and is believed to have beneficial effects; how he was, on leaving the neighborhood, loaded with flowers, the only thing they had and knew would please him, has charmed me intensely. To admire a great man for his professional labors eagerly undertaken and successfully carried out, is a great satisfaction to the scientific observer; to be able to love him, in addition, for his philanthropy and warm-heartedness, is a feast of the soul."

Even these various duties were not sufficient for his active mind, and hence we find that since 1862 he has taken an active part in the work of the German legislature, and for more than twenty years has been an alderman in the Berlin City Council. It need hardly be stated that VIRCHOW, with his liberalizing scientific training has been opposed to the absolutism of BISMARCK.

It is given to but few to rival VIRCHOW as he rivaled GOETHE, in scientific work, but another form of greatness, no less to be admired, can be reached by the many, a form of greatness not absent from VIRCHOW.

FOTHERGILL says of his friend, DR. ALEXANDER RUSSELL, who settled in Aleppo: "The Pacha himself became acquainted with the merit of our deceased friend, consulted him, called

him, his friend, found him upright, sensible and sincere; as a man polite without flattery; decent but not servile; as a Christian, true to his principles; disinterested and generous as a Briton; and in point of skill as a physician superior to every one. A natural, even, cool and consistent temper, a freedom of behavior as remote from confidence as from restraint, improved by reading and conversation; a mind imbued with just reverence to God, and impressed with a sense of the duty we owe; an understanding fraught with the principles of the profession to which he had been early devoted, happily blended with great benevolence, was a character seldom to be met with in the Asiatic regions. This, however, was the character of our colleague."

EDITORIAL NOTES.

GROSS-VIRCHOW.—Soon after the return of Dr. S. D. Gross from his visit to England, where had been conferred upon him the degree of D.C.L. by the Oxford University, it was our pleasure to congratulate him as being the recipient of so many distinguished honors, and that this last seemed a fitting crown and recognition of a long and successful professional career. His reply was: Would you know the highest and most gratefully received compliment ever bestowed upon me? It was when I first visited Virchow's clinic: Virchow was at the time lecturing to the class. An attendant took in my card. Virchow looked at it and hastened to the door where he greeted me, and bringing me forward with both my hands clasped in his, introduced me to his class as the Father of Pathology, and author of the first work ever printed on that subject, and of which he paid me a most profound compliment. I tell you that was one of the proudest moments of my life.

ST. LUKE'S HOSPITAL AT DENVER, COLORADO.—This handsome new structure for the care of the sick was consecrated under the ritual of the Episcopal church, conducted by Bishop Spalding, on Sunday, October 18. The wards are four in number, containing fifty beds, and there are fourteen private beds; there are two beds endowed for charity cases. The present structure will eventually be the administration building, when the planned wards are added. The outlay thus far has been about \$80,000 for land and central building.

SOCIETY PROCEEDINGS.

Mississippi Valley Medical Association.

Seventeenth Annual Meeting, held in St. Louis, Missouri, October 14, 15, and 16, 1891.

(Concluded from page 701.)

SECOND DAY—AFTERNOON SESSION.

Dr. J. W. Carhart, of Lampasas, Texas, contributed a paper on

THE INFLUENCE OF GRAVEYARDS ON PUBLIC HEALTH,

in which he drew the following conclusions:

1. From whatever standpoint this subject is approached it must be with care and gentleness, since the graveyard, though a constant menace to public health, has a pseudo sacredness fostered by the profoundest sentiments of our natures.

2. The method of the disposal of the dead should be founded on reason and not on custom or sentiment.

3. The interment of the dead in the earth was never enforced by a statute, Jewish or Christian, and was merely incidental to both dispensations.

4. No law, human or divine, requires us to dispose of the dead in a manner prejudicial to the health and comfort of the living.

5. Whilst it may be an open question as to the right of the State to decide as to the manner of the disposal of the dead, except in exceptional cases, it is clearly the province and duty of the State to prevent such disposal as will in any wise jeopardize the interests of the living.

6. From all the facts at our command, we are led to the conclusion that the graveyard should become a thing of the past, and that incineration is the method most in accordance with science, sanitation, æsthetics, reason and religion.

7. We would add, as a corollary to these several conclusions, that since the intelligent, broad-minded physician is the almost exclusive guardian of public health in seeking to prevent the development and spread of disease, it is plainly his duty, when cemeteries are being located, to use his best endeavors to have them so placed as to jeopardize as little as possible the public health; and for its moral effect he should encourage efforts to beautify existing cemeteries; and that he should seek, as fast as possible, without too much violence to the tender sensibilities of the masses, to encourage incineration of the dead, or some other method more in harmony with sanitary science than the common modes now practiced.

Dr. J. T. Jelks, of Hot Springs, Ark., read a paper on *Blennorrhœa*.

Dr. Landon Carter Gray, of New York, followed with a paper on *The Present Aspect of Cerebral Surgery*, in which he epitomized the work of Horsley, Ferrier, Keen, and others.

Dr. John A. Larrabee, of Louisville, Kentucky, read a paper entitled *The Importance of Recognizing a Temporary Rachitic Condition in Infants*.

Dr. F. C. Hoyt, of St. Joseph, Mo., read a paper entitled

PACHYMEINGITIS HÆMORRHAGICA INTERNA,
WITH REPORT OF A CASE AND PRESENTATION
OF A PATHOLOGICAL SPECIMEN,

and suggested the following deductions, offering them as a practical and rational view of the subject:

1. That the disease known as pachymeningitis hæmorrhagica interna chronica is not a disease of the dura mater primarily, and not necessarily at all. The name is therefore a misnomer, and the simpler term sub-dural hæmatoma should be substituted.

2. That the condition is due primarily to paralysis or loss of the normal vaso-motor tonus, associated with structural changes in the cerebral vessels, particularly those of the pia mater.

3. That hæmorrhage may, and often does, take place in the substance of the dura from the causes stated in this paper, but that its vascular supply and anatomical structure render it improbable that these hæmorrhages play any part in the formation of a sub-dural hæmatoma.

4. That the hæmorrhage occurs from the vessels of the pia mater primarily, forces its way without difficulty through the upper web-like layer formerly called the arachnoid, escaping into the sub dural space. The extravasated blood becomes organized, new vessels are formed, and these assist in furnishing the recurrent hæmorrhages.

5. That the inflammation of the internal surface of the dura mater is secondary, and due to the irritation of the extravasation, and then is not general, but occurs only in patches where organic union has taken place.

Dr. Seth S. Bishop, of Chicago, read a paper entitled

CAMPBOR-MENTHOL IN CATARRHAL DISEASES.

(See page 639, JOURNAL of Oct. 24).

Dr. F. King, of New York, read a paper in which he advocated the poro-plastic felt jacket in the treatment of spinal troubles.

SECOND DAY—EVENING SESSION.

The Association was called to order at 8 P.M., by the second Vice-President, Dr. S. S. Thorn, of Toledo, Ohio, after which President Hughes delivered his address on

MEDICAL PROGRESS.

(See page 651, JOURNAL of Oct. 31.)

Dr. J. B. Hamilton, of Chicago, followed with an address on

THE DRAINAGE OF CHICAGO,

in which he principally dwelt upon its topography. (See page 639, JOURNAL of Oct. 24.)

Dr. Joseph M. Mathews, of Louisville, Ky., delivered a timely, entertaining and remarkably humorous address on the

LIGHTS AND SHADOWS OF A DOCTOR'S LIFE.

The address was punctuated throughout with great applause, and was a relief to the laity after listening to the profound, scientific, and scholarly addresses of the preceding speakers.

At the close of the session the members repaired to the Lindell Hotel, where a banquet was given with all the manifestations of true St. Louis hospitality. Dr. I. N. Love was toastmaster.

THIRD DAY—MORNING SESSION.

Mr. Chas. Truax, of Chicago, read a paper (by invitation) entitled

ARE CONSERVATIVE AMPUTATIONS ALWAYS IN
THE INTEREST OF THE PATIENT?

He said that during the past quarter of a century the development of prosthetical science has advanced with a rapidity unprecedented in the history of the art. The first of the two great causes which stimulated this development may be found in the dreadful carnage and mutilation observed in the late civil war, which left thousands of veterans maimed by the loss of one or more limbs, for whom it was necessary to provide artificial substitutes. Experience and investigation had convinced him that the percentage of favorable cases can be largely increased, provided surgeons will familiarize themselves with the necessary mechanism of ordinary artificial legs, and the relations existing between them and the stumps on which they are to be worn, and select their point of amputation accordingly.

From a statistical point of view he finds that out of 2,135 tibial amputations reported to him as being performed between the years 1885 and 1891, 90.7 per cent. resulted in healthy stumps; 3.1 per cent. of stumps upon which compensative appliances could not be worn. Of these tibial cases, 962 were seen by the surgeons after they were wearing, or had attempted to wear, an artificial limb, 86.9 per cent. of which walked with an easy movement and a comparatively graceful step. Of 658 tarsal and tibio-tarsal amputations reported at the same time, 82.7 per cent. resulted in sound healthy stumps; 8.3 per cent. underwent re-amputation, while 3.2 per cent. died, leaving 14 per cent., including re-amputation, upon which prosthetical apparatus could not be worn.

He recommended surgeons to avoid amputating within three inches of the knee-joint. Do not amputate between the meta-tarsal bones and the junction of the lower and middle thirds of the tibia. At all other points they should save all they could, and they will have done in every case, the best for their patients.

INTESTINAL OBSTRUCTION.

This was the title of a paper read by Dr. Henry H. Mudd, of St. Louis, in which he advised early operation.

Dr. C. H. Dalton, of St. Louis, read a paper entitled:

TEMPERATURE NO GUIDE IN PERITONITIS.

So skeptical had he become on the subject that, in considering the advisability of an operation in abdominal cases, he was no longer guided by the thermometer. He takes the temperature in all cases, but does not let the lack of fever influence him against operation when other symptoms, upon which he has learned to place far more reliance, would move him in the opposite direction. Surgeons found it difficult to convince the average physician that a violent peritonitis may exist without a normal, or even subnormal, temperature, for the teaching by some has heretofore been that sepsis is always accompanied by an elevated temperature.

Several weeks since, he was called in consultation in a case of intestinal obstruction, in which peritonitis was in full blast. He advised operation, and was met with the objection that there could not be much peritonitis with a temperature of 99.5°. He pointed in vain to the patient's anxious countenance, to the great tenderness on pressure, a distended belly, the vomiting, the pulse, as well as the fact that purgatives had been tried without avail. The doctor in attendance insisted upon one more dose of salts. It was given. It did not move the bowels, but did move the patient to that place from which no traveler returns. Time and again he had seen cases of intestinal obstruction with stercoraceous vomiting, rapid pulse, anxious countenance (facies abdominalis), in which the temperature was about normal or even subnormal. In his earlier experience, the lack of fever in abdominal cases puzzled him very much, and led him astray in a number of instances. While it is well to remember that fever, when present in belly cases, indicates peritonitis, its absence does not warrant us in saying that peritonitis is not present, and should not blind us as to the actual condition.

SARCOMA OF THE DORSO-SCAPULAR REGION.

Dr. Geo. N. Lowe, of Randall, Kas., read a paper on this subject. He reported a case upon which he had operated, the patient, a man aged 18 years, with no history of tuberculosis, carcinoma or sarcoma, recovering. The object of this paper was to show:

1. The necessity of an early operation in all cases of a malignant growth.

2. That some species of sarcoma are more rapid and destructive in their course than carcinoma, especially the spindle- and giant-celled variety.

3. The necessity of having a law to enforce patients so afflicted, as soon as a correct diagnosis can be made, to an early operation, thereby preventing great suffering and prolonging life.

4. That a sarcoma which has grown to an enormous extent, infiltrating the surrounding tissue at any considerable extent from the main growth with cell proliferation, an operation is almost useless as regards a permanent cure.

Dr. W. H. Link, of Petersburg, Ind., read a paper on

APPENDICITIS,

and offered the following conclusions:

In the commencement of the attack, give salines often and liberally until the gut is completely emptied. Advise perfect rest in bed. Forbid any but liquid nourishment. If pain is severe, apply counter-irritation and dry heat until salines act. If patient improves, wait. If pulse grows worse, if temperature rises, if pain increases, if tumefaction becomes larger, if tenderness becomes more marked, operate. At no time give morphia, but consider an increase of pain sufficient to demand relief by opium an imperative, unequivocal and emphatic indication for surgical interference.

RHEUMATISM AND GOUT AS FACTORS IN THE CAUSATION OF ECZEMA, AND THE MANAGEMENT OF THOSE CONDITIONS,

was the title of a paper by Dr. A. H. Ohmann-Dumesnil, of St. Louis. He did not purpose speaking of the etiology of eczema. The only phase which he desired to take under consideration was, in how far rheumatism and gout were concerned in the causation and prolongation of eczema, and what was the proper management of those conditions in order to derive the greatest benefit, so far as the cutaneous involvement is concerned. Naturally this implied that he was about to sustain the position that the conditions named were etiological factors, and such was probably the case. If we took the trouble to examine critically the history, condition, treatment and results in patients, a mass of evidence would be found which, if it did not constitute absolute proof, bore so much weight with it that the probabilities would all tend to confirm and strengthen the position that rheumatism and gout prolong, intensify, and even cause eczema. He had found it to be quite frequent, also, to note that an acid condition was present in eczematous patients. It occurred too frequently to be regarded as a coincidence. Moreover, a correction of this acid condition finds its good effect reflected in the ease with which the cutaneous trouble gave away to proper medication. Whether such cases were inclined to rheumatism or gout it was difficult to say; but that an excess of acid was found in all of these conditions there was no opportunity of denying. For, if eczematous pa-

tients were interrogated in this respect, a large proportion of them would speak of acid eructations, pyrosis, and other evidences of the condition.

In regard to the management of gout and rheumatism volumes had been written, and equally good results had been claimed for different methods of treatment. The most powerful alkali to affect the solubility of uric acid was, beyond all doubt, lithia. The urates of that alkali are the most soluble known, and on that account, a better elimination can be secured. Potash salts run next in value in regard to their solvent value upon uric acid. The soda salts, while exercising good influence, are not as valuable in this respect as either of the others, and the magnesia salts are the least effective.

A question of no mean importance was that concerning the solubility of the various alkaline salts. Chemical investigation has clearly demonstrated that the bicarbonates of lithia, potash and soda are not only the most soluble, but the most easily assimilated by the animal organism. To prevent any decomposition, it is only necessary to dissolve them in carbonated water, which not only keeps them in a soluble state, but also adds to their palatability.

Dr. Enno Sander, of St. Louis, has prepared his well-known lithia potash water, which fills all the indications required, and which acts not only as an anti-rheumatic, anti-lithic, and anti-gouty mixture, but constitutes a grateful table water as well. It not only acts as a curative remedy, but, what is still of greater importance, it is a reliable prophylactic. Its composition is as follows:

Lithium bicarbonate, gr. xiiij.
Magnesium bicarbonate, gr. x.
Potassium bicarbonate, gr. xvj.
Sodium chloride, gr. x.
Carbonated water, gr. xvj. *℥*.

This quantity, one pint, should be taken daily, or the amount increased, it being necessary.

Conditions occasionally arise in which it will be found that a mixture of salicylate of soda and bicarbonate of soda will effect the happiest results in rheumatism, and occasionally in gout. Given in carbonated water, the administration is made pleasant, and the mixture has an effect upon the patient which is refreshing at the time it is taken, and which effects beneficial results in a very short time. When eczema is present, the proper local remedies should be made, and it is astonishing how their action will be accentuated by the internal use of alkalies as indicated above.

Dr. C. A. L. Reed, of Cincinnati, Ohio, read a paper entitled

OBSERVATIONS ON THE MANAGEMENT OF UTERINE TUMORS,

in which he said that there are certain solid tumors of the uterus which require no operation. They are, for the most part, comparatively small

neoplasms, either interstitial or sub-serous; they are indolent in growth, and they do not produce alarming symptoms from either pressure or hæmorrhage. There are certain other myomata of the uterus that are uniformly recognized as demanding operation. They are, for the most part, rapidly growing tumors in young subjects—removable fibro-cystic tumors, soft œdematous tumors, large bleeding fibroids, and those growths which give rise to ascitic accumulations.

Dr. Reed offered the following conclusions:

1. That all persistently hæmorrhagic uterine myomata, of whatever variety, should be advised to early operation.

2. In young subjects, with multi-nodular tumors, giving rise to alarming hæmorrhage, the appendages should be removed when practicable as an alternative for extirpation. But the latter operation should be done whenever the character of the growth will permit of its removal by dangers less than those which would be involved by its continuous existence.

3. To those tumors already recognized as demanding operation should be added those of uterine development that are liable to dangerous constriction by the uterine walls, and in which their destruction by this means might induce sepsis.

4. All cases of subserous growths, indolent yet progressive in character, in which the tumor has become a menace to neighboring organs, should, whether hæmorrhagic or not, be advised to exploratory incision with reference (1) to removal of the appendages, or (2) of the neoplastic organ.

5. All growing tumors, growing in women beyond the menopause, should be removed, if possible, by vaginal total extirpation, or, if that be impracticable, by abdominal section.

6. All distinctly operable cases demanding interference should be advised to submit to operation at the earliest practicable moment.

THE ETIOLOGY AND TREATMENT OF GRANULAR CONJUNCTIVITIS.

This was the title of a paper contributed by Dr. Francis Dowling, of Cincinnati, Ohio.

Dr. Dowling stated that the great rôle which the disease plays in the causation of blindness renders its successful treatment one of the great desiderata of our day. Its great hot-beds are in some of the countries of the Orient, owing to the prevalence of whirlwinds of sand and the intense heat and glare of the sun. The malady attacks by preference the poorer classes; the rich and well fed enjoy a comparative immunity from the disease. It is most frequent in persons between the ages of 15 and 45, and children under 6 rarely have the disease. It does not become epidemic at a height of over 250 meters above the sea level, and it loses its contagious character at this height.

Treatment.—Personally, he had had more success by touching the lids with the mitigated stick of ergent. nit., and then immediately washing it off, than with any other remedy. He applied the treatment usually twice a week, and on the intervening days he rubs in an ointment composed of yellow oxide of mercury and atropia. He also corrects any trouble of refraction that may exist, for unless this is attended to, the disease will persist under all kinds of treatment.

The disease is now treated in Paris, France, by completely everting the lid, and scarifying the granular tissue, then rubbing in with a stiff brush a $\frac{1}{500}$ solution of bichloride of mercury. Cases are cured in this way in four to six weeks, that formerly took several years to cure with the old treatment. In outbreaks of the disease in orphan asylums, barracks, etc., the afflicted should be completely isolated from the healthy inmates, and their apartments should be kept absolutely clean, and fumigated with burning sulphur at least once a week.

Dr. John Bartlett, of Chicago, presented a paper in the form of a

REVIEW OF AN OBSTETRICAL WORK,

published in Paris in 1682 by Paul Portal. He said the older members of the profession had for years rested in the opinion that it was Paul Portal to whom obstetrical science was indebted for the discovery of the fact, that in placenta prævia the after-burden was attached to the womb, and had not simply fallen down over it, as was taught by writers before his day.

Dr. G. Frank Lydston, of Chicago, followed with a paper entitled

OBSERVATIONS ON URETHRAL STRICTURE,

in which there were many striking points. The author opposed the general impression prevalent among surgeons that the long duration rather than the severity of a virulent urethritis determined the development of organic stricture. He claimed that this view has been due to fallacious reasoning from the standard of *post hoc ergo propter hoc*. It is not the long continued urethritis that produces a deposition of the adventitious tissue constituting organic stricture. On the contrary, a chronic localized urethritis exists because the stricture or the foundation of it has been determined at some portion of the urethra by the primary virulent inflammation. He claimed that the liability to the formation of organic stricture is directly proportionate to the severity of the primary inflammation. The localization of stricture, the author claimed, was not due, as Sir Henry Thompson and his school assert, to an obstruction to drainage and the retention of the products of virulent inflammation, but to deficient elasticity or distensibility of the canal at certain points. The conditions determining

stricture he compared to those prevailing in a rubber tube about which cords are tied in such a manner that while some actually constrict the tube, others simply prevent its distension. If fluid be pumped through a rubber tube thus constricted or restricted, as the case may be, at a certain degree hydrostatic pressure, and at certain intervals, friction, occurs at these points and a continual unrest. The epithelium is rapidly removed, its vitality being impaired by the virulent poison of urethritis. By and by rapid removal and reformation of epithelium becomes a cell habit, the resulting formation of cells being of a low grade of inherent vitality. In addition to this change upon the surface of the mucous membrane there is deposited young connective tissue cells in and about the affected point as an evidence of an attempt on the part of Nature to secure rest and prevent strain. These cells the author likened to sandbags thrown up to strengthen or prevent a breach, as the case may be, in a fortification.

The doctor called attention to a number of interesting reflex phenomena incidental to stricture of the urethra. He also went exhaustively into the various toxæmia conditions incidental to renal disturbance secondary to stricture, and to that peculiar form of toxæmic incident to the absorption of ptomaines from the site of the urethral lesion. He went into the subject of electrolysis and absolutely denied the possibility within the limits of safety of using it in the treatment of organic stricture. Galvanism, he claimed, instead of electrolysis, is what is really accomplished. He condemned the routine and extreme claims of Newman, and also the other extreme as represented by Dr. Keyes, who asserts that galvanism, *i. e.*, so-called electrolysis, has absolutely no effect. Dr. Lydston claimed that the effect of galvanism upon organic stricture of the urethra was the same in its physiological character as upon healthy or morbid tissue in any other situation. The author described what he terms *plus* conditions of organic stricture. Thus we have engrafted upon the organic foundation varying degrees of hyperæmia, spasm, and œdema, one or all. These *plus* conditions, the author claimed, galvanism, properly applied, would subtract from the organic condition in certain cases, and in so far as this effect was marked the stricture would be benefited. The author denied the possibility of the galvanic current producing absorption of fibro-connective tissue after it has arrived at the acme of differentiation by any current which will not destroy the mucous membrane itself; in other words, we cannot control the galvanic current so that it will exert a selective action and remove the abnormal tissue while sparing the normal tissue.

The following officers were elected:

President—Dr. C. A. L. Reed, Cincinnati, Ohio.

First Vice-President—Dr. C. S. Bond, Richmond, Ind.

Second Vice-President—Dr. Thomas Hunt Stucky, Louisville, Ky.

Secretary—Dr. E. S. McKee, Cincinnati, Ohio.

Chairman of the Committee of Arrangements—Dr. Joseph Ransohoff, Cincinnati, Ohio.

Place of next meeting, Cincinnati, October, 1892.

DOMESTIC CORRESPONDENCE.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

In the possession of some descendants of John Murray, who was treasurer of the New York Hospital, nearly a hundred years ago, there are some very interesting reports of that venerable institution in its early days which your correspondent has lately had the opportunity of examining. These reports, or rather circulars of information, which are naturally yellow with age, but in an excellent condition of preservation, are printed on a single sheet of four quarto pages. The first of them commences as follows:

NO. 1. CHARITY EXTENDED TO ALL. STATE OF THE NEW YORK HOSPITAL FOR THE YEAR 1797.

Below this is a wood-cut of the hospital building on lower Broadway, the front of which was about 125 feet in length. Then comes a list of the officers and governors, and this is followed by the names of the medical staff, the descendants of some of whom are still prominent in the profession of this city. The physicians were John R. B. Rodgers, Elihu H. Smith, Samuel L. Mitchell and David Hosack, and the surgeons, Wright Post, Richard S. Kissam, Samuel Borrowe, Richard Bayley and Valentine Seaman. The house-surgeon was Dr. Samuel Barnum, and the steward rejoiced in the name of William Hogsflesh. The names of the apothecary and matron are also appended.

The circular goes on to state that this institution was undertaken by private subscription of the inhabitants of New York, in the year 1770, and in consequence of a petition to the then governor by Peter Middleton, John Jones and Samuel Bard, three reputable physicians of this city, was incorporated by charter on the 13th of the sixth month (June), 1771, under the style and title of "The Society of the Hospital in the city of New York, in America." A few extracts from the early history of the hospital as given in this report may prove of interest:

"Animated by the Principle of christianity, the Society uniformly disclaimed any influence of contracted attachment to any national, civil or religious Distinctions; but that all Persons should be entitled to the Benefits of the Institution, whose Maladies and extreme Indigence cast them on the Charity of others for Relief. By the Influence of Doctor Fothergill and Sir William Duncan it was aided by the Contributions of many Inhabitants of London and other Parts of Great Britain; the Legis-

ture also aided the Institution by an Allowance of Eight Hundred Pounds annually, for Twenty Years, and a Plan of a Building, suggested by Dr. John Jones, was agreed upon in 1773, but unfortunately when the House was almost completed, it accidentally took fire on the 28th of the second month (February), 1775, and was nearly destroyed. By this Calamity the Society sustained a loss of Seven Thousand Pounds, and their Intention would perhaps have been suspended, had not the Legislature almost immediately voted them the sum of Four Thousand Pounds to assist in repairing their loss and rebuilding the House; but the War with Great Britain, which took place in the same year, prevented its completion; and during the War the House was occupied by Barracks, and much injured by the British Garrison. Owing to a Variety of Obstacles, and the Derangement in the Circumstances of our Citizens during the War, it was not until the first month (January), 1791, that the House was in proper order to receive Patients; at which Time a Number were received. The Annuity granted previous to the War by the Provincial Legislature having ceased with the Commencement of Hostilities, except an Allowance for Four Years of that Annuity, which was paid the Society out of the Excise since the Peace, the Legislature in 1792 granted Two Thousand Pounds a Year, for Five Years, as a Consideration of Arrears due, for its better Support. In the Second Month (February), 1793, the Act for allowing Two Thousand Pounds was repealed, and the Sum of Four Thousand Pounds was granted for Five Years annually, and in the second month (February), 1796, this was increased by adding the further Sum of One Thousand Pounds per annum, for Four Years. By an Act of the Legislature, passed 1st of the fourth month (April), 1796, entitled, 'An Act more effectually to regulate the Port of New York,' the Harbour-Master is directed to pay to the Hospital certain fines therein mentioned."

"Notwithstanding all these generous allowances," the report goes on to say, "the Governors have not been able to complete the necessary Arrangements, owing to certain alterations, repairs and improvements that had to be made about the buildings and grounds." We read next that persons laboring under incurable decrepitude, or long continued ailments of any kind, were considered as fitter objects for an almshouse than for this hospital, "which is properly an Infirmary, for the Reception of such Persons as require 1st, Medical Treatment. II^d. Chirurgical Management. III^d, Maniacs, and IVth. It is in Contemplation to fit up a Laying-in Ward, for the Reception and Accommodation of poor and distressed pregnant Women, so soon as Circumstances shall permit."

That the value of such an institution as a school for clinical instruction, and the necessity for a good medical library, was appreciated at this early date, is shown by the following extract: "The Students who attend the Lectures of the Medical Professors of Columbia College likewise attend regularly the Practise of the Hospital, which has thus become a valuable Addition to the excellent Medical Establishment of that Seminary; the Benefit derived from Attendance on the Cases of the Sick is

very much promoted by the Clinical Lectures delivered on the more select Objects of Practise by Dr. Rodgers, whom the Medical Faculty of the College have appointed to that Employ. And that the Interest of Letters and Science might be as much attended to as possible, the Governors have voted the sum of Two Hundred Pounds as the Beginning of a Library, to be composed of Books on Medical and Chirurgical Subjects, and on such Philosophical and Oeconomical Matters, as have a Connection therewith, so that the Governors themselves, as well as the Physicians and Surgeons of the Hospital, may have the best of information on all needful Occasions, and the means of acquiring Knowledge be greatly facilitated to Students of Physic and Surgery." From this it will also be seen that the recent consolidation of the College of Physicians and Surgeons with Columbia College, is only a return to the condition of affairs existing in the good old times a hundred years ago. It is interesting also to read the record of the actual starting of the great New York Hospital Library, which has since become so famous all over the medical world: "By the Care and Pains of Doctors Mitchell and Smith, the Purchasing Committee, a very select and valuable Collection of Books have already been made; and, it is earnestly to be hoped, the Funds of the Corporation will be found commensurate to the annual Appropriation of a Sum of Money for this valuable Purpose."

On the third page of the report is given an abstract of the financial accounts of the hospital for the current year, and on the fourth page a summary of the medical and surgical cases. During the year 1797, the total number of patients treated was 578, of whom 240 were natives of America and the rest of foreign birth. The largest number of cases of any one disease is set down to syphilis, viz.: 127. Third on the list as regards numbers comes pneumonia. Of this disease there were 59 cases, of which 24 were cured, 2 were discharged by desire, 13 died, and 20 still remained under treatment at the end of the year. Only six cases of phthisis were noted. Of course, the name typhoid does not appear on the list, but we find eight cases of typhus, of which two died. The diagnosis of "tumor," without designation as to the seat or character of the growth, is given in three cases. There were two cases of cancer, of which one is marked cured and one relieved.

From the report for 1800 we find that the number of patients treated had almost doubled during the three years, the total during that year being 1103. Of these, no less than 306 had syphilis. This year there were but 20 cases of pneumonia. In addition to 10 cases of *fever and ague*, 16 cases of *intermittent fever*, and 2 cases of *remittent fever*, we find 43 cases set down simply as "fever," without any indication of the nature of the fever. As the name typhus does not appear on this list, and as 12 of the patients died, it seems probable that these were for the most part cases of typhoid. On the list of diseases appear *anasarca*, 1 case; *ascites*, 2 cases; and *dropsy*, 10 cases. This year there were 15 cases of small-pox and 4 cases of measles.

P. B. P.

NECROLOGY.

DR. CHRISTOPHER JOHNSTON, of Baltimore, died October 11, in his 70th year. His family had been Baltimorean since 1766, and he was the third of his name. He was an alumnus of the University of Maryland in the year 1844. He was chosen to a chair in his *alma mater* in 1864, and built up a fine reputation as an artistic and instructive teacher, having great facility with pencil and brush. In 1870 he succeeded the late Nathan R. Smith to the much-coveted chair of surgery. For a decade at least, he was regarded as among the first in this branch; in his studies he showed a strong preference to microscopy and pathology. He was a frequent contributor to the Medico-Chirurgical Faculty of Maryland, being its president in 1876. He was a member of this Association from 1855.

DR. DAVID H. STORER, of Boston, died September 10, in his 88th year. He was one of the senior ex-presidents of the American Medical Association, having held the chair at the Baltimore convention in 1866. Dr. Storer was eminent as a scientist as well as a physician and medical teacher. A fuller biographical minute is in course of preparation and may be expected in an early issue.

DR. THOMAS T. PRATT, who died at the University Hospital, London, August 29, was an Alabamian by birth, who had resided abroad almost continuously since the close of the civil war. He was a son-in-law of the late Professor Marion Sims, and built up a large practice in Paris. During the last fifteen years he had resided in London. He served with distinction in the Franco-Prussian war, and obtained crosses or decorations from both nations after the war was over.

MISCELLANY.

"The Lancet" on American versus European Medical Education.

We have more than once directed the attention of our readers to the state of medical education and of the medical colleges in the United States, and to the regulations of the schools and licensing boards of the profession. It requires but a slight acquaintance with the members of the profession in America who visit us, and with American literature and journalism, to see that there must be many sources of good medical education in the States. We are apt perhaps to be somewhat prejudiced by the newspaper accounts which reach us of fraudulent colleges and bogus degrees, and the facilities for their existence and prosperity in the very constitution and law of the States are unfortunately too great. If we refer to them, it is in no unfriendly spirit to our brethren in America. On the contrary, our exposure of them is supplementary to their own efforts in that direction. There is in the States, as we have frequently pointed out, a wide and earnest attempt to expose and remove the defects of their system and to lift the whole standard of medical education to a European level.

We have before us a very interesting paper by Samuel O. L. Potter, A.M., M.D. (Jeff.), Professor of the Princi-

ples and Practice of Medicine in the Cooper College of San Francisco, read before the forty-first annual meeting of the American Medical Association. The paper, which is headed *American versus European Medical Education*, after comparing American medical college work with that of European medical schools, seems to be an honest endeavor to demonstrate that the result is by no means so unfavorable to the American schools as is generally assumed. Dr. Potter is very indignant at what he calls the feeling of contempt for American medical education and persons, which, he says, so "pervades the European that, polite as he is, he is never able wholly to disguise it." He is especially angry with the action of the authorities of the medical school at Berlin in denying to American graduates studying there the right to the letters M.D. after their names. And he suggests as punishment that American students should withdraw from Germany, and for post-graduate study visit London or Edinburgh, where he thinks they will benefit more directly than in Berlin or Vienna. But he goes further and suggests retaliatory legislation refusing recognition to foreign graduates until the American diplomas are recognized.

We sympathize with Dr. Potter and all other earnest colleagues of his who are doing their best to put medical education on a proper footing throughout the States, and who are conscious of the disrespect which, meant for the worst American diplomas, is very apt to affect the best of them. But we venture to suggest that he will attain his object sooner and better represent the just dignity of medical teaching authorities in the United States by a little fuller admission of the difference between the process of medical education in the States and in European countries, and a little longer perseverance in the efforts which he and the representatives of other American schools are making to lessen that difference, which is practically admitted by himself. It is not only in details, but in the absence of a central controlling power in the States. In European countries the State acts from a center and as a whole. In England, in addition to the central legislature unifying medical laws for England, Ireland, and Scotland, there is the General Medical Council, controlling and supervising all the medical examining boards. Dr. Potter speaks kindly of England, and naturally looks to her for recognition. We cordially reciprocate the sentiment that the great English-speaking nations should in this, as in all matters, honor and respect each other. But he will take it well from us when we confess that he has not established to our satisfaction that the American is equal to the European curriculum.

In respect of the *time* required for medical education in England and the States, respectively, we can not follow him when he tells us that, inasmuch as the conjoint medical colleges of England allow a *year and a half* of the four years' time they require to be spent in receiving instruction as a pupil of a legally qualified practitioner, thus leaving only two years and a half for school and hospital work, they do not so favorably differ from the American colleges, which always require a year's pupillage previously to their two or three years' college work. We do not find such a permission in our reading of the regulations of the English colleges. They specifically require "that not less than three winter and two summer sessions shall have been passed at one or more of the medical schools recognized by the two colleges." We know as a matter of fact that men can only enter the profession after a preliminary examination, and that from whatever board, university or college students in England take their qualification, they have to work four years for it in consecutive sessions, and to pass very trying examinations before they succeed. Moreover, we would remind Dr. Potter that the General Medical Council has this year decided that the term of medical education must extend over *five* years, and has not sanctioned the use of more than six months of this time in the way of pupillage. We have said that the exposure of the de-

fects and faults of American medical schools and boards is the work of American physicians and surgeons who are jealous of the honor of their profession, and who, in many instances, as Dr. Potter says of the president and founder of the Cooper Medical College, of San Francisco, have made great sacrifices for it. He avers "that each member of his college gives ten hours a week to college work, exclusive of the hours spent in preparation, and not one draws a cent from its treasury." This is very noble, but it has no bearing on those scores of colleges which swarm in the States, whose diplomas are given after two or three years' study, and with little or no preliminary education. If any one doubts the evil, let him invest in one of the most instructive medical publications in the world, The Report on Medical Education of the Illinois Board of Health—one of the States which is blessed with a legislature that has given, as all States should give, to a medical board the power of judging diplomas, and refusing recognition to unworthy ones. This report abounds in information as to the conditions of medical education in the United States and Canada, and its able compiler, Dr. Rauch, can have no interest in misrepresenting the facts. He points out that in the seven years reported on there has been very great improvement. There has been a steady rise in the number of colleges requiring proofs of preliminary education, and of colleges requiring a more extended period of medical education. There is a yearly decrease in the percentage of graduation to matriculation in the United States. Another feature of the American case is the existence of examining and licensing bodies which do not give instruction. These are all marks of an improvement which is bound to go on as public and professional opinion on the subject is strengthened. The effect of the Illinois State Board raising the minimum requirement for diplomas to be recognized in that important State was to diminish considerably the number of students and of graduates. It is inevitable that when men can get diplomas on easy terms elsewhere, they will not repair willingly to those boards which exact higher terms. The great hindrances to progress in the States are the inequality of requirement and the number of schools and degree-granting bodies without central law or control. There are still 135 medical colleges of all kinds in the United States. Each State has its own medical bodies, and the powers of these vary in each State. In some, as in Illinois, there is an act of the State empowering a medical board to grant medical qualifications. In others there is no law on the subject. In a great many States diplomas are merely registered in a county clerk's office. In others bodies seem to form and to dissolve again, or to merge into other bodies with functions of a teaching or diploma-granting kind in a most remarkable way. One has only to study the history of the schools, even of a leading State, to see how much too easy it is for schools to be formed. In the State of Pennsylvania, for example, where the medical faculty dates back to Franklin's time, and was chartered mainly by his influence, sixteen schools of various kinds could until lately be counted. Nine of these, fortunately, are extinct, some having been guilty of fraud of the worst kind. These are the evils incidental to a system of government by separate States. We rejoice at the efforts made to mitigate and remove them, and wish such endeavors all success. But it is obvious that such a loose system, and one so open to abuse, exists nowhere in Europe.—*London Lancet*, Oct. 3, 1891.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.—Programme of the Fourth Annual Meeting, to be held in the hall of the House of Delegates, Richmond, Va., on November 10, 11 and 12, 1891. Members of the medical profession are cordially invited to attend. First day, Tuesday, November 10. Morning session, 9.30 o'clock. Address of welcome and response.

1. Albuminuria: Its Relation to Surgical Operations, by J. W. Long, M.D., Randleman, N. C.
 2. On Systemic Infection from Gonorrhœa, by Bedford Brown, M.D., Alexandria, Va.
 3. The Neuroses of the Genito-Urinary System in the Male, by G. Frank Lydston, M.D., Chicago, Ill.
 4. The Principle of Drainage as Applied to the Surgery of the Deep Urethra, by F. W. McRae, M.D., Atlanta, Ga.
 5. A Report of Some Additional Cases of External Perineal Urethrotomy Without a Guide, by J. Edwin Michael, M.D., Baltimore, Md.
 6. The Proper Method of Performing Circumcision, by W. Frank Glenn, M.D., Nashville, Tenn.
 7. Reduction of Dislocations by Manipulation, by W. F. Westmoreland, M.D., Atlanta, Ga.
Adjournment at 1 o'clock P.M.
Afternoon session at 2.30 o'clock.
 8. Drainage in Endometritis and Salpingitis, by W. M. Polk, M.D., New York, N. Y.
 9. Complications in Pelvic Surgery, and How to Deal with Them, by Joseph Price, M.D., Philadelphia.
 10. Laparotomies Performed During the Past Year, by Thomas Opie, M.D., Baltimore, Md.
 11. A Case of Pelvic Abscess, by John Brownrigg, M.D., Columbus, Miss.
 12. Ovarian Cysts, with the Report of a Case of Ovariectomy in a Young Girl, by C. Kollock, M.D., Cheraw, S. C.
 13. Abdominal Section in a Case of Cyst of the Mesentery, with Remarks, by J. A. Goggans, M.D., Alexander City, Ala.
 14. A New Method of Diagnosis in Disease of the Sigmoid Flexure, by Joseph M. Mathews, M.D., Louisville, Ky.
- Second day, Wednesday, November 11. Morning session, 9:30 o'clock.
15. A Medico-Legal Aspect to Pelvic Inflammation, by W. W. Potter, M.D., Buffalo, N. Y.
 16. Medico-Legal Aspect of Intestinal Surgery, by J. D. S. Davis, M.D., Birmingham, Ala.
 17. Peritonitis from a Surgical Standpoint, by A. V. L. Brokaw, M.D., St. Louis, Mo.
 18. Hand Disinfection, by Howard A. Kelly, M.D., Baltimore, Md.
 19. Cataphoric Treatment of Uterine Fibroids by Iodide and Other Agents, by Hunter McGuire, M.D., Richmond, Va.
 20. The Pedicle in Hysterectomy; How Formed; Its Subsequent Behavior; Its Final Condition, by I. S. Stone, M.D., Washington, D. C.
 21. Clinical Importance of Skin Dimpling in Carcinoma of the Female Mamma, by L. McLane Tiffany, M.D., Baltimore, Md.
 22. Early Diagnosis of Carcinoma by the Microscope, by H. Berlin, M.D., Chattanooga, Tenn.
Afternoon Session at 2:30 o'clock.
 23. The President's Annual Address.
 24. On Injuries to the Pelvic Floor and the Method of Repairing the Same, by Thomas Addis Emmet, M.D., New York.
 25. The Part the Shoulders Play in Producing Laceration of the Perineum, with Suggestions for its Prevention, by W. D. Haggard, M.D., Nashville, Tenn.
 26. The Surgical Treatment of Anterior Displacement of the Uterus, by C. A. L. Reed, M.D., Cincinnati, O.
 27. The Growth of Fibroid Tumors of the Uterus after the Menopause, by Joseph Taber Johnson, M.D., Washington, D. C.
 28. Thinness of Uterine Walls Simulating Extra-Uterine Pregnancy, by Geo. J. Engelmann, M.D., St. Louis, Mo.
- Third Day, Thursday, November 12. Morning Session, 9:30 o'clock.
29. Tracheotomy for Foreign Bodies, with Cases, by W. O. Roberts, M.D., Louisville, Ky.

30. A Method for Removing Impacted Gallstones by means of Solvents, by Robert T. Morris, M.D., New York.

31. Cholecystotomy—Report of Case—Fifty-two Gallstones and 10 Ounces of Pus Removed—Recovery, by W. B. Rodgers, M.D., Memphis, Tenn.

32. Treatment of Gallstones, with Report of Cases, by W. E. B. Davis, M.D., Birmingham, Ala.

33. Nephrectomy, with Report of Cases, by Edwin Ricketts, M.D., Cincinnati, O.

34. The Present Status of Cerebral Surgery, by Landon Carter Gray, M.D., New York.

35. The Treatment of Injuries of the Skull, by W. H. Hudson, M.D., LaFayette, Ala.

36. Some of the Complications of Psoas Abscess, by J. McFadden Gaston, M.D., Atlanta, Ga.
Afternoon Session, 2:30 o'clock.

37. Venomous Serpents of the United States, and the Treatment of Wounds Inflicted by them, by Paul B. Barringer, M.D., University of Virginia.

38. The Female Urethra, by K. P. Moore, M.D., Macon, Ga.

39. Bleorrhœa in Women, by J. T. Jelks, M.D., Hot Springs, Ark.

40. Hæmorrhage *versus* Shock, by W. L. Robinson, M.D., Danville, Va.

41. Imperforation of the Rectum, by Geo. Ben. Johnston, M.D., Richmond, Va.

42. Senile Gangrene, by Frank Prince, M.D., Bessemer, Ala.

43. A Case of Induced Abortion for Relief of Nausea and Vomiting, with Remarks, by Christopher Johnston, M.D., Richmond, Va.

Railroads: Those who attend the meeting must obtain from the ticket agent at the point of starting a certificate that they have paid full fare to Richmond. These certificates will be signed by the Secretary of the Association at Richmond, and upon his certificate a return ticket will be issued at one cent per mile.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from October 24, 1891, to October 31, 1891.

Capt. Charles Richard, Asst. Surgeon U. S. A., is relieved from duty at Ft. Logan, Col., and will report in person to the commandant of the Military Prison, Ft. Leavenworth, Kan., for duty.

Capt. Louis M. Mans, Asst. Surgeon U. S. A., relieved from duty at Whipple Bks., Ariz., and ordered to Ft. Apache, Ariz., for duty.

Capt. Victor C. Biart, Asst. Surgeon U. S. A., having been found incapacitated for active service on account of disability incident to the service, is, by direction of the President, retired from active service, to date October 21, 1891.

First Lieut. Robert R. Ball, Asst. Surgeon U. S. A., granted leave of absence for one month, with permission to apply for an extension of one month.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending October 31, 1891.

Surgeon Henry P. Harvey, ordered to receiving ship "St. Louis."

Surgeon James M. Flint, detached from Smithsonian Institution, and to the U. S. S. "Miantonomah."

Surgeon T. C. Heyl, detached from receiving ship "St. Louis," and wait orders.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Two Weeks Ending October 24, 1891.

Surgeon George Purviance, upon completion of duties as chairman of examining board, to inspect Marine-Hospitals at St. Louis, Mo., Cairo, Ill., and Cincinnati, O. October 16, 1891.

Surgeon John Godfrey, to represent the Service at the meeting of the American Public Health Association. October 14, 1891. To inspect Marine-Hospital at Louisville, Ky. October 14, 1891.

P. A. Surgeon H. R. Carter, granted leave of absence for thirty days. October 17, 1891.

P. A. Surgeon W. J. Pettus, orders to Norfolk, Va., revoked; to proceed to Cape Charles Quarantine for temporary duty. October 14, 1891.

P. A. Surgeon J. J. Kinyoun, to represent the Service at the meeting of the American Public Health Association. October 17, 1891.

P. A. Surgeon T. B. Perry, to proceed to Norfolk, Va., for temporary duty. October 14, 1891.

Asst. Surgeon G. M. Guitierrez, to proceed to Gulf Quarantine for duty. October 20, 1891.

Asst. Surgeon M. J. Rosenau, granted leave of absence for thirty days. October 24, 1891.

ORIGINAL ARTICLES.

A CASE OF IDIOPATHIC SPINAL HÆMORRHAGE.

Read before the Section of Medical Jurisprudence and Neurology, at the Forty-second Annual Meeting of the American Medical Association, Washington, D. C., May 6, 1891.

BY THEODORE DILLER, M.D.,

FELLOW OF THE PITTSBURGH ACADEMY OF MEDICINE.

Hæmorrhage into the spinal cord of traumatic origin, while not of very frequent occurrence, has been noted often enough to establish the fact of its occurrence beyond a doubt. But as to whether hæmorrhage into or about the cord may take place without an antecedent traumatism some writers are in doubt. However, the majority of writers do admit that idiopathic spinal apoplexy may occur, but they are all in accord in stating that the affection occurs only very rarely.

In view of these facts I trust the case I am about to relate will prove to be of some value as tending to place the existence of the disease beyond the peradventure of a doubt.

Although the case is incomplete inasmuch as no post-mortem record is included, yet I believe the clinical history alone will be sufficient to establish the diagnosis.

T. K., a laborer aged 51 years, had been in robust health and worked steadily up to the date of present illness. He is a tall man of rugged frame; habits of life good; never had syphilis nor any prolonged illness; heart normal.

March 12, 1891, after performing his ordinary day's work he went to bed feeling as well as usual. But instead of going to sleep in a few minutes as had been his habit, he remained awake, turning about the bed uneasily until 11 o'clock, when he was suddenly seized with an excruciating pain at about the first lumbar vertebra, which radiated from thence around the abdomen and down the thighs. He at once arose from bed in the intensity of his agony and rapidly walked up and down the room. After a few minutes he sat down upon the edge of the bed and bathed his feet in hot water which his wife had brought for him. While thus engaged, became nauseated and attempted to vomit several times but did not succeed. The gastric distress

lasted only a few minutes. While his feet were yet in the water he noticed that they were becoming "numb," and told his wife about it. Upon attempting to stand up, soon afterwards, he became conscious of a diminution of power in his legs. He became greatly alarmed at this discovery and at once got into bed, and became aware, a few moments later, of the entire loss of motion and sensation in both legs. The pain rapidly lessened in intensity so that he was entirely free from it twenty-five minutes after the initial attack. The patient feels sure that his consciousness, his memory for words and ability to utter them, was never lost or even impaired during the attack. Members of his family bear him out in this statement. They are further in accord in stating that at no time was the motion or sensation in any of the organs above the umbilicus impaired. The loss of voluntary control of the bladder and bowels was noticed the next day and must have occurred coincidently with the paraplegia.

A critical examination the next day revealed the following conditions: Paralysis of motion complete in both legs; power in the abdominal muscles greatly impaired; anæsthesia of all kinds completely lost in both legs, impaired over lower half of abdomen. Patient is unable to expel urine or fæces; was not aware that both bladder and bowels needed emptying. No impairment of mental functions; no pain; motion and sensation in muscles of upper half of body unimpaired.

Subsequent history.—Pain never returned, save for an occasional twinge. Urine and fæces taken away regularly by mechanical means. The paralysis as described continued unchanged until about April 4 (three weeks after initial symptom) when the first signs of the return of muscular power were noted. Patient could at that time move toes of left foot. From this time up to the present date (May 1) there has been steady progress towards recovery. He can now move both legs about the bed, flex knees and thighs. Sensation has largely returned. He is not yet able to expel his urine and fæces, although the desire to micturate and defecate now comes to him.

Remarks.—The very sudden onset of the symptoms would preclude the possibility of the trouble being due to tumor, aneurism, bone disease

or myelitis. An embolus would produce sudden symptoms, but it would be highly improbable that trouble of this kind could cause such a complete condition of paraplegia in less than half an hour. So I am forced to conclude that the lesion was a hæmorrhage—and a large one—either in the cord itself or in the structure immediately surrounding it. I am inclined to think the hæmorrhage occurred in the cord itself. As to the part of the cord involved, the symptoms would indicate the lower part of the dorsal region.

THE DIAGNOSIS OF TRAUMATIC LESIONS IN THE CEREBRO-SPINAL AXIS AND THE DETECTION OF MALINGERING REFERRED TO THIS CENTRE.

BY B. A. WATSON, A.M., M.D.,

CONSULTING SURGEON TO THE BAYONNE HOSPITAL, SURGEON TO THE JERSEY CITY HOSPITAL, ETC., JERSEY CITY, N. J.

The counterfeit can not be detected without an accurate knowledge of the genuine, and in addition to this an exact knowledge of the counterfeit, and likewise a definite knowledge of the difference between the genuine and counterfeit, is still imperatively required.

It therefore follows that he who would attempt to detect malingerings should always be able to diagnose concussion of the brain and spinal cord. The proper performance of this task requires a full knowledge of the etiology, semeiology and pathology of the morbid condition under consideration. Let us, therefore, direct our attention to these essential factors of diagnosis—carefully analyzing each—in order that we may more thoroughly comprehend their relation and bearing on each other. It is universally admitted that concussion of the spinal cord most commonly follows falls upon the feet, buttocks, less frequently on the hands when both arms are outstretched, gun-shot wounds involving portions of the spinal column, a stroke of lightning, heavy blows delivered over the bones of the pelvis or in the line of the spinal column, etc. The direct effect of these falls and blows is the production of contusions of the soft parts, etc., which are more or less disorganized by these traumatic agents. The force of these agents is not by any means entirely expended in the production of these contusions, but there will be carried along the bony structure a vibratory motion which will also be imparted in varying degrees to the adjacent soft parts. A very fair idea may be gained of these vibratory movements by placing the hand on the apex of a bell, suspended in the air, while its base is struck with a metallic hammer; or by the touch of a properly keyed string of a musical

instrument when it has been put in motion. The same vibratory motion may be likewise very well illustrated by tapping gently with the finger on a glass jar or other vessel which is partially filled with jelly, and then watching the tremulous movements imparted to the contents by the slight blows delivered on the vessel. The attention of the medical profession has been very frequently called to the peculiarities of concussive or vibratory force by French authors, but its physiological and pathological action has never received that careful study to which it is entitled. A very important factor, which presents itself for our consideration in connection with study of this force is, the fact that it is not transmitted equally well by the various organs and tissues of animal bodies; and, consequently, a direct blow delivered on one part of the body may be entirely negative or result in the production of very little vibratory action, while on another part of the organism the results will be very marked. Thus a blow delivered directly on the nates will give rise to the concussive force and be transmitted along the spinal column to the bony walls of the skull, and from this structure to the brain itself, which is in such close contact with these bones. A portion of the same force will likewise be expended in varying degrees on those organs which are in intimate contact with this line traversed by the traumatic agent. The functional disturbances and the pathological changes in the various organs will depend on the physiological functions, weight, texture, etc., of the parts involved, which need not be enumerated here. A blow delivered on the feet, while the lower extremities are extended, will be transmitted to the bones of the pelvis, and then along the spinal column. A somewhat similar result may possibly be produced by a fall on the hands when the arms are extended; however, the force of this blow will be much diminished by reason of the anatomical differences in the parts, particularly the less intimate connection between the bones of the arms and the spinal column, than that which exists between the bones of the lower extremities and this important highway for the transmission of concussive force. It should likewise be remembered that the more concentrated the direct traumatic force, *i. e.*, the smaller the area to which it is applied, the greater will be the amount of concussive force generated while the other factors remain unchanged. Thus a blow covering an area of four square inches delivered directly over any part of the spinal column will generate far more concussive force than it would if spread over the whole posterior region of the body. In fact, in the former case, if the blow was a severe one, functional derangements and pathological lesions might be rationally expected to follow from the concentrated nature of the concussive

force, but in the latter they will be looked for in vain. There is a very marked difference between the concussion in the case of gunshot wounds produced by musket or rifle balls, and that which follows heavy blows or falls—in the former the pathological changes are more circumscribed, while in the latter they may be considered general. Thus a musket ball having found lodgement in the vertebral column, which has in some degree impaired its outer surface without producing any lesion of the osseous tissues within the canal, the spinal cord will be frequently found in an ecchymotic state at a point approximating to the lesion in the spinal column. In connection with this subject, it may be further stated that no single blow,—however great its momentum—delivered on the anterior surface of the thorax or abdomen, could be rationally expected to produce concussion of the spinal cord, since its force would be almost entirely expended on the visceral organs within these cavities. The study of the effects of lightning, and likewise those of electrical currents of both a high and low degree of potency—possess for the surgeon, in connection with the consideration of concussive force, very great interest. The vibratory character of electrical currents is apparently identical with the other forms of concussive force; and, furthermore, it is readily demonstrable that the physiological action, functional disturbances and pathological changes likewise possess essentially the same characteristics. The fact has long been recognized by the ablest authorities that concussion is physiologically indicated by a nervous and circulatory excitation or depression. In accordance with this opinion Verneuil has given the following definition of concussion: "A series of phenomena more or less sudden followed by a mechanical disturbance of the anatomical elements, tissues and organs, characterized by a temporary excitation or a depression of the functions of the parts disturbed, and likewise producing anatomical changes which are generally observed in cases of functional activity or repose." Mechanical concussive force, like lightning strokes and electrical currents, may produce every possible degree of concussion, varying from the slightest functional disturbances, which pass off within a few seconds, to instantaneous death. Further similarity on the effects of these agents is shown by the fact that concussion and even death may be produced by rapidly repeated mechanical blows or a rapid succession of electrical strokes, while a single impulse would be scarcely sufficient to cause even temporary functional disturbance. The pugilist knows that the blows which will promptly render his antagonist unconscious should be delivered on his head. He therefore seizes the head of his enemy and delivers on it in rapid succession blow after blow until his object is accomplished. Experimentation on

animals has shown that concussion of the brain may be caused by slight taps delivered on the head in rapid succession with a hammer, etc.

In our consideration of the etiology of concussion of the cerebro-spinal axis we have said little in regard to its causation in the brain. It is probably understood, however, that those agencies which have already been mentioned are the important factors in its production in this organ as well as the other organs of the body. The same general laws pertaining to the etiology of this morbid condition are as applicable here, as elsewhere; consequently a blow delivered on the head will be more efficacious in the production of concussion of the brain than would be the concussive force had it been transmitted to this organ from some other part of the body. Furthermore, the weight of this organ and other anatomical peculiarities of the same, must receive due consideration. In this attempt to describe the symptoms of concussion in the cerebro-spinal axis, we immediately encounter a difficulty arising from the fact that the functions of the organs are materially different; and, consequently, the symptoms observed in connection with a traumatism in the spinal cord, will produce entirely different symptoms from those found when a similar lesion exists in the brain. The remedy for this difficulty is very simple, and only requires that the symptoms be separately noted as they pertain to lesions in the different organs. A much more serious obstacle is found in the combination of all sorts of injuries with those of *pure* concussion, especially those having their origin in fractures, dislocations, sprains, rupture and stretching of ligaments, particularly in the spinal column, and likewise with the concussion in one organ, the symptoms of which are erroneously attributed to this morbid condition in another. In illustration of the above mentioned error, I desire here to call attention to the fact, that hæmaturia is frequently mentioned as a symptom of concussion of the spine, while I have *conclusively shown* by my experiments on animals, that it bears no constant relation to lesion of the cord, but on the contrary, following concussive accidents, *indicates a concussion of the kidney*. Furthermore, visual changes are frequently attributed to concussion of the spine, while as a matter of fact, the lesions on which these changes depend are situated either in the brain or the eye. I am now prepared to assert that the greater part of the organs within the thorax and abdomen are equally as liable to suffer from concussive force as the brain itself; and likewise that concussive accidents are much more frequent in these visceral organs than in the spinal cord. This assertion is based on the fact, that these lesions are entirely analogous to those observed in the brain, merely requiring that the proper allowance be made in these organs for differences

in weight, texture, etc., factors which must be taken into consideration in connection with the study of the lesions of concussion in the brain and spinal cord. Furthermore, every true concussion takes its origin in the same peculiar force. Therefore, if it is desirable to speak of concussion of the brain, spinal cord, etc., why should it not be applied to the lungs, liver, kidneys, etc.? Would it not be absurd to speak of gunshot wounds of the brain and spinal cord, while the term is withheld from analagous lesions caused by the same peculiar force in other parts of the body? There has recently been made an attempt to employ the term "*nervous shock*" instead of concussion; but this departure possesses *no advantage* and has already caused much confusion. No attempt is here made to deny that certain portions of the nervous system participate in the concussion; although it is self-evident that the functional disturbance and pathological lesions are primarily developed in connection with the *circulatory system*. These preliminary comments are made in preference to any attempt at the mere enumeration of symptoms, which, in order to possess real value, must be fully stated and explained. It should likewise be remembered that there are different degrees of concussions, and these differences are indicated by a corresponding difference in symptoms.

It must now be apparent that the limits of this article compel me to economize space, so far as it can be done without defeating the object for which it was written. Permit me, therefore, once more to call attention to the fact, that concussion always produces either excitation or depression, *i. e.*, functional activity or repose. The former condition possesses practically little interest, if observed immediately after the application of the concussive force, since it is commonly of short duration, and does not require any attempt at treatment. However, there is another form of excitation occasionally observed in severe cases of concussion of the brain, which commonly makes its appearance from twelve to forty-eight hours after the receipt of the injury. This condition is indicated by a full pulse, flushed face, throbbing of the carotids, headache, dry and hot skin, photophobia, noises in the ears, and sometimes marked drowsiness. These symptoms point to the existence of cerebral hyperæmia, which is commonly of short duration; but in some cases it is the prelude to inflammation of the brain. In the severe cases of concussion of the brain or spinal cord, the *prompt appearance of symptoms indicative of depression*, commonly suggests the existence of organic lesion, rather than mere functional disturbances; while, as a general rule, the degree of danger is fairly expressed by the depression. It should, however, be remembered that the symptoms of depression, in order to possess any special value, must pertain especially to

the functions which are known to be performed by these organs. Therefore diminished consciousness, although the patient may be aroused sufficiently to answer questions, the pupils contracted or dilated, relaxation of the sphincters, a feeble and irregular pulse, shallow and sighing respirations, a cold, pale and clammy skin—point very clearly to the brain as the seat of the injury, when the symptoms have followed promptly after the application of concussive force. The symptoms following those recorded in the above belong to the reactionary period; the object of this paper does not require that they should be mentioned here. Concussion of the spinal cord is most commonly indicated by the appearance of paralytic symptoms, which frequently involve the lower extremities—especially the motor power, and likewise, in many cases, also the sensory. Therefore, in our experiments made on dogs, our attention was promptly directed to the movements of these animals immediately after the application of the concussive force.

The following facts possess an important bearing on the subject now under our consideration. In a recent summary made from my "Experimental Study of Lesions arising from Severe Concussion," I shall here venture to cite the following: "Paraplegia is a very important indication of a lesion of the spinal cord, and may have its origin either in a disease or traumatism. This morbid condition may be either complete or incomplete, and when due to disease, it is commonly slowly progressive; but if due to a traumatism, it is rapidly manifested, and soon reaches its fullest development. In support of this statement, examine the following facts: The whole number of cases in which pathological changes were found in the cerebro-spinal axis were fifty; the whole number of cases in which any indications of these lesions were observed during the life of these animals were thirty-three, while our record shows that in the last mentioned class there were twenty-three cases of paraplegia."

It will here be observed that there were ten cases in which there had been noted during the lifetime of these animals some indications of a traumatism, but which did not exhibit during that period paraplegic symptoms. It is also worthy of notice that in every instance these paraplegic symptoms were observed immediately after the application of the concussive force, and furthermore, that in all cases of complete paraplegia there was not a single case which subsequently improved. In the large majority of cases of incomplete paraplegia there was commonly some improvement observed during the first three days, but in a few instances the paraplegic symptoms became more marked during the first twenty-four hours; however, even these cases soon showed signs of improvement. It is not claimed

that even the immediate appearance of paralytic symptoms after the application of concussive force, in all cases establishes the existence of pathological lesions in the spinal cord. I am strongly impressed with the idea that an injury of the peripheral nerves may be followed by temporary and commonly local paralysis. A certain degree of importance should be attached to the existence of either anæsthesia or hyperæsthesia in all cases where lesions of the spinal cord are suspected. The existence or absence of pain in these cases—especially true concussion of the spinal cord—possesses very little interest for the diagnostician. In fact, the existence of pain and soreness ought probably to be looked on as having their origin in a contusion, sprain or wrench, involving the vertebral ligaments, muscles, etc., rather than indicating lesions of the cord. Having now presented a few of the characteristic symptoms of true concussion of the brain, and likewise of the spinal cord, I desire to add in this connection, that it is certainly very unfortunate for the science of surgery, that hitherto it has been the custom of nearly all authors, writing on what they have unfortunately designated as "concussion," to group together half a dozen or more traumatic conditions, differing radically from each other in their etiology, semeiology and pathology. It requires no prophet to assert positively that so long as this grouping is continued there will be a want of clearness in all these articles—that theory will be frequently introduced in the place of scientific facts, that clinical observation will continue to mislead the profession, that good-natured authors, believing that all their predecessors in writing on this subject have told a little truth, will still further add to the existing confusion in their attempts at compounding these incompatible ideas. Let me ask what would be the inevitable result, if medical authors should group together under the unfortunate cognomen of "Smith's disease" scarlatina, diphtheria, rubeola, roseola, variola, typhus fever, etc.? However, this combination is no more objectionable than that grouped under the name of "railway spine," which is so frequently employed by many of our surgical authors even at the present time. However, the dawn of a new light may be approaching, since Dr. John A. Lidell, in writing on "Injuries of the Back, Including those of the Spinal Column, Spinal Membrane, and the Spinal Cord," states that "the traumatic lesions of the back naturally arrange themselves in three groups, as follows:

1. Injuries of the integuments and muscles, or soft parts generally.
2. Injuries of the vertebral column.
3. Injuries of the spinal membranes, spinal cord and spinal nerves.¹

It must be apparent to any one that this classification presents many important advantages over that which is so commonly employed. Another serious source of confusion has arisen from the fact, that the term concussion, in former times, was restricted in its application to the brain—although analogous pathological lesions were produced by the same force in nearly all the organs of the body.

Furthermore, concussion was badly defined by the old authors; since the term was used to indicate a condition induced by a more or less violent shaking of the brain, whereby serious symptoms were produced without lesions of the structures.

Recent experiments on animals and a careful study of this subject have entirely failed to support their statements in regard to the non-existence of lesions after concussive accidents in the brain and spinal cord. The results of my experiments were very conclusive in regard to the existence of these lesions. There were fifty cases in which pathological changes were observed in the cerebro-spinal axis, but only thirty-three of these cases showed any symptoms during life of injury of this centre; it will therefore be readily seen that in seventeen cases, although pathological lesions existed, they were not made apparent by symptoms which could be recognized on the animals. It is likewise important to state in this connection, that there was not a single case observed during all of our experiments in which we even suspected the existence of concussion of the cerebro spinal axis where we failed to discover pathological lesions by our subsequent examination—*post-mortem* or *microscopical*. These pathological lesions, in true concussions, are certainly unique in character and nearly or quite pathognomonic in their signification. The only lesions which bear semblance to the pathological changes of concussion, are those arising from contusions, and these are localized, and not distributed generally throughout the organ, which is commonly the case in the former morbid condition. However, there is found an exception to these rules in the case of concussion following gunshot wounds, in which the injury is commonly localized and resembles more or less closely the ecchymotic appearance arising from contusions. The functional disturbances and the pathological lesions are clearly shown in my experiments, to have had their origin in the vaso-motor system. In order to illustrate the pathological changes in the spinal cord which have been observed to follow in a mixed or complicated case of concussion of this organ, I will here cite the report of an autopsy, etc.,² made on the body of a coal-porter who died thirty-four hours after the accident.
